LECTURES
ON
THE CHEMISTRY OF THE POISONS;
OR ON
PRACTICAL TOXICOLOGY.
SHOWING THE APPLICATIONS OF CHEMISTRY TO THE DISCOVERY OF CRIME.

By H. LETHEBY, M.B., Lond:
Lecturer on Chemistry at the Medical College of the London Hospital, &c.

LECTURE I.

Objects of the course.—Importance of the study of Toxicology.—Assistance it gives to the medical practitioner when in the witness-box.—Its importance in a more general point of view.—Its bearing on the public health and safety.—Frequency of the crime of poisoning.—Circumstances which tend to favour the development of the crime; indiscriminate sale of poisons; use of poisonous pigments for confectionery; unwholesome food, &c.

It is my intention, gentlemen, to occupy a portion of your time, during the ensuing summer session, in making a practical inquiry into the leading facts connected with *chemical toxicology*. In other words, I propose that you should be engaged in conducting an experimental examination of the physical and chemical properties of the various poisons, and in ascertaining the respective values of those important processes which have, from time to time, been introduced as a means of effecting the qualitative or quantitative determination of such substances.

We shall thus, I hope, be enabled, not only to obtain an insight into the duties of the chemico-legal analyst, but also to perceive the many difficulties which beset his path, and to learn in what manner these difficulties may be overcome.

And, gentlemen, in order to incite you to take a lively interest in the work which will thus devolve upon us, let me entreat you to consider that your reputations may be, at some time, deeply concerned in it; for, as the active practice of your profession must often lead you to the discovery of crime, so it must bring you into relation with the forum, and expose you to the dangers of the witness-box.

Some of you may, perhaps, regard these dangers as light matters, and may think that a good general knowledge of your Profession will, at all times, bear you harmless through them, and enable you to defeat the purposes of an acute, and too often merciless, advocate. But, allow me to apprise you of the fallacy of such an opinion, and to remind you, that in by far the greater number of cases in which your reputation will be so assailed, the touchstone will be applied, not to the groundwork of your knowledge, but rather to the frail and more subordinate portions of it; and, although I will not go the length of asserting that the instances are few in which medical witnesses have come down from such an ordeal without suffering more or less injury to their reputations, or that no one has ever gained a positive increase of credit therefrom, yet I hesitate not to say, with a high authority on this question, that there is not any position in which a medical man can be placed in which his character is so powerfully menaced, or his personal convenience so seriously interfered with.

All this, gentlemen, arises from the deep responsibility of your offices as Medical men, and from the high value which is very properly attached, by both judge and jury, to your professional opinions; for, remember, it is to you that the agents of justice ever turn, in the expectation of your being able to throw a light on the difficulties which surround a grave charge of poisoning; it is upon you that the innocent ground their hopes of acquittal, and the guilty their dread of conviction; and it is to you that the public also appeal, in order to find protection from the designs of the secret murderer. But if, after you have been engaged in some serious judicial inquiry of this kind, it should be found, through the test of a rigorous cross-examination, that you are deficient, not only in Professional knowledge, but in common prudence also, that, in fact, you are altogether unequal to the performance of those highly important duties which you may have, perhaps most rashly, undertaken, then, gentlemen, you will feel the bitterness of disappointment and of self-reproach, and will have to encounter all the sad results which are sure to flow from the possession of a counterfeit and ill-grounded reputation.

Let me, moreover, remark to you, that the events which I have just pictured are not by any means uncommon; for, in the course of a very limited experience, it has been my lot to witness the discomfiture of more than one Medical man, who had placed themselves in such an unfortunate predicament; and who were compelled to endure, as Dr. Gordon Smith says, the scrutiny and displeasure of the bench, the browbeating of the bar, the derision, the contempt, and the laughter of the audience, the discontent of their friends, the disgrace cast by them on their Profession, the exposure of the public Press, together with all the pernicious consequences which have followed to their reputation and fortune.

If, however, such considerations as these do not furnish you with a sufficiently strong inducement to become conversant with practical toxicology, let me urge you to study it on another account, namely, on account of the great public good which your services therein are capable of effecting; for, as you will soon perceive, there rests with you, and, I might say, almost with you alone, a means of suppressing one of the most fearful, as well as one of the most common of crimes; namely, that of secret poisoning. That this is a common crime is evidenced by the records of the public press, and by the experience of all who are actively engaged in medico-legal pursuits. If we turn to the reports of the Registrar-general, we may perceive that about 600 deaths from poison occur annually in this country; but, great as this number is, it does not, in my opinion, at all represent the mortality which actually results from this cause. I believe, indeed, and shall soon take an opportunity of showing, that by far the greater number of deaths from poison are attributed to other causes, and therefore elude all public inquiry. Nor am I singular in holding this opinion; for it is stated by Mr. Taylor, in his recent work on poisons, that he believes the practice of slow poisoning by arsenic to be more frequent in this country than is commonly supposed; and he adds, that it behoves practitioners to be exceedingly careful in their diagnosis, inasmuch as the usual characters of arsenical poisoning are completely masked.

Again, it has been remarked by a writer in a late Number of the *British and Foreign Medico Chirurgical Review*, that the present enormity and extent of this crime have never been equalled in any period of history.

In touching, therefore, on this most important subject, I do consider it to be my duty to allude, somewhat freely, to a few of the circumstances which appear to me to favour the development of this crime; for, by so doing, I may possibly enable you to expose its enormity, and, at the same time, help you to put a check upon its practice.

Among the circumstances to which I refer is—

1st. *The facility with which poison may always be obtained.*—This is a notorious fact, and it is also a serious one, for we may regard it as being at the very root of the evil to which I have been alluding. Indeed, it has been discussed and commented on again and again, not only by the Editors of our Medical Journals, but also by the writers of other and more powerful periodicals; but, for all this, the Legislature cannot be persuaded to impose any restrictions on the present system of free trade in such deadly drugs. It is not, however, in London, nor in our large metropolitan towns, that we have an opportunity of witnessing the full amount of danger which is incidental to this system of trade; but it is in the rural districts, among the poor, the ignorant, and the careless, that the peril is manifested to the greatest extent; for, in those districts, laudanum may be purchased by the gallon, and arsenic by the pound, without any inquiry being instituted as to the object of such purchases. In corroboration of this, I may mention, that, when I was at the trial of Sarah Scarborough, which took place at Cambridge during the Lent Assizes of 1848, I heard it given in evidence by one of the witnesses, a druggist of March, that he was accustomed to sell to the people of that town as much as two pints of laudanum weekly. He sold it, he said, in pennyworths, and he never asked [illegible]ing the purpose to which it was to be put, b[illegible] he knew that it was commonly taken for the p[illegible]pose of procuring sleep. He admitted, also, [illegible] there were other druggists in the town who sold much more of the drug than he did? I recollect, also, that, when I was at Wisbeach, on an inquest, about eighteen months since, I heard it stated by a clergyman of the district, that the habit of taking laudanum was just as common with the people of that place. In fact, it was remarked, just about that time, by the Editor of the *Lincoln Mercury*, that the practice of taking narcotics was increasing most fearfully in the counties of Cambridgeshire and Lincolnshire, and that old and young were equally its victims. "It may," said the Editor, "be safely averred, that every second customer who visits the druggist, purchases opium, laudanum, or some such drug;" and he went on to state, that, in the town of Wisbeach alone, there were upwards of 400 gallons of laudanum sold and swallowed every year—a quantity which amounts to eight gallons per week. Nor is this free trade in poisons carried on by the druggist alone; for, in many country places, grocers, drapers, and oilmen are the chief retailers of such substances, and, as I hardly need inform you, their *reckless* traffic therein has, and ever must give rise to very serious consequences. No later back than the year 1847, when one of these worthies (an oilman) was examined at a trial at Guildford, he admitted that laudanum and Godfrey's cordial were sold at several shops in that town in common with grocery, cheese, and drapery; and he remarked, with all the *naïveté* in the world, that he would not swear that they did not keep arsenic, prussic acid, and other deadly poisons, among their articles of grocery. A medical journalist, in commenting on the above fact, has added, that, not long since, a superintendent of police went, in disguise, to a general shop in a country village, and asked for twopennyworth of arsenic. It was immediately weighed out to him in the very scales in which coffee, tea, and other articles of food were usually served, and handed to him by an old woman who kept the shop. Upon his asking her whether she was not in the habit of marking "*Poison*" on substances of this kind, her answer was, "Lor' bless you, I can't write, to begin with; and then it would frighten people if 'poison' were written on it." This experiment was made in order to show the facility with which arsenic might be obtained, in quantities sufficiently large to destroy a hundred people. And, by way of offering a further proof of this fact, I may refer to the recent case of Mary Ann Cullen, who poisoned her three brothers, her mother, a woman, and her child—in all, six persons; and who, according to her own confession, procured the poison from a druggist of Wexford, to whom she applied for some drug to kill rats. He told her that he could not sell her less than six-pennyworth, so she purchased this quantity and took it home with her. Some time afterwards she paid the druggist (Mr. Croghan) another visit, and, according to her account, he looked very sharply at her, and asked her what she wanted.' She said, "the same complement for the rats." He then inquired if the last did good, and, on handing her another sixpenny packet, his observations were, "Stick to it, and it will banish all the *rats*."

Such a dangerous condition of things as this is, calls loudly for public consideration; and it must be corrected before we can expect to put a stop on the crime of secret poisoning. Already Mr. Farr, the Deputy-Registrar-General, has drawn attention to it; and, in commenting upon the crime to which it gives rise, he says, that it must be admitted, by all who have paid attention to the subject, that the system of pharmacy in England requires revision. The sale of prussic acid, opium, nux-vomica, oxalic acid, corrosive sublimate, and arsenic, to the public, may be either prohibited altogether, or permitted only by medical prescription. The master's certificate

may be required for sugar of lead, and those poisonous substances which are employed in the arts and manufactures. Nor is this an impracticable suggestion, for the French Government have for a long time past acted upon a similar principle. In the Royal Ordinance which was issued in the month of October, 1846, it is required, that the vendors of poisons shall be licensed by the Mayors of their respective communes, and that all purchases and sales of such substances, together with the names of the buyers and sellers, and full particulars concerning the purposes to which the poison is to be applied, shall be inscribed in a special register, and be indorsed by the Mayor or Commissary of Police.

Again: a pharmacian is not permitted to sell a poison, or to dispense it, without an order from a physician, a surgeon, an officer of health, or a veterinary practitioner; and it is required, moreover, that the pharmacian shall immediately register the order or prescription, then sign it, and finally attach his seal to it. It is also required, that certain poisonous substances, of which the pharmacian is furnished with a list, shall be kept apart from ordinary drugs, that they shall be secured by means of a lock, and be dispensed only by the chief himself. In fact, every effort is made by our continental neighbours, to suppress the unlawful use of poison, and so to protect the lives of the citizens of France, not only from criminal attempts, but also from the deplorable errors which are so likely to result from an unrestricted trade in such substances.

Other suggestions have also been made in the hope of effecting these desirable objects. Thus, it has been proposed to mix certain colouring, strong-smelling, and noxious tasting substances with the commoner poisons. M. Tizot recommends that vermillion, creosote, and colocynth should be mixed with them. The Editor of the *Medical Gazette* has suggested the use of prussiate of potash, and sulphate of iron or copper, which, upon the addition of water, will give rise to the production of a blue or purple compound. The Council of Salubrity of Paris has advised the employment of Prussian blue, and nux-vomica; the former of which serves to colour the poison, and the latter to render it exceedingly bitter. Morever, the Professors of the Ecole Nationale Veterinaire, of Alfort, and of the Ecole de Pharmacie, have proposed that all arsenical preparations which are used, either for the treatment of diseases in cattle, or for the destruction of vermin, or for the preparation of skins, shall be prepared and coloured in accordance with certain formulæ which they have issued, and these propositions have been approved of by the Minister for Agriculture and Commerce. So that there is in France, at the present time, a three-fold restriction concerning the public sale and use of poisons, namely, a restriction which is founded on a good system of registration; 2ndly. A restriction which prohibits the use of arsenic for agricultural purposes; and 3rdly. A restriction as regards the employment of poison for the destruction of vermin, the preparation of skins, and the cure of cattle. In these respects, therefore, the legislators of France are very much in advance of our lawgivers; and they have set an example which our Government would do well to follow.

Another source of great mischief to the public is, the employment of improper and unwholesome articles of food, such as confectionery, sweetmeats, bon-bons, &c., which are coloured by means of poisonous pigments; thus arsenite of copper, or Scheele's green, is commonly employed to impart a rich green tint to these substances; orpiment, or chromate of lead, is used to give them a yellow colour, and vermillion to produce a bright red tint. Many of you can, I dare say, remember the disaster which happened last summer at a public dinner in Nottingham, where several gentlemen were poisoned in consequence of their partaking of a blanc-mange, the top of which was ornamented with a green device in imitation of a cucumber. This device had, unfortunately, been coloured green by means of arsenite of copper. A case of a like nature is recorded by Mr. Hetley, the visiting surgeon of the St. Marylebone Infirmary. He was called to the assistance of three adults and eight children, who were poisoned by two-penny-worth of confectionery which had been coloured by means of Scheele's green. And Dr. Guy, in his Toxicological Report for 1848, states that an accident of the same character, though on a larger scale, had also come within his experience. An ornamental green basket, after having been used at an evening party, was given to one of the attendants, who distributed the fragments among the inmates of a large workshop. Severe vomiting and purging were the result. On inquiry at several confectioners Dr. Guy found that arsenite of copper is commonly used to give a green colour to confectionery; and an analysis of a fragment of the basket confirmed this statement.

Again, I have frequently had to investigate cases in which individuals have been poisoned through the use of bad food, such as putrid sausages, cheese, fish, and mouldy flour, all of which substances, notwithstanding that they are known to be unwholesome, are permitted to be sold, and to be distributed without any restriction whatever, among the helpless poor of this country. Surely we ought to have some legislative enactment, in order to put a stop to such dangerous practices.

I shall, Gentlemen, in my next lecture, proceed further with the consideration of this important subject.

LECTURES
ON
OPERATIVE OPHTHALMIC SURGERY.

DELIVERED AT THE CENTRAL LONDON OPHTHALMIC HOSPITAL.

By H. HAYNES WALTON, Esq., F.R.C.S.,
Surgeon to the Hospital, and to the St. Pancras Royal General Dispensary.

LECTURE I.

Object and nature of the course—Qualifications for an operator—Classification of cataract—Rejection of the term spurious cataract—Pathological changes occurring in cataract—Advantage of dilating the pupil in examining the eye—Cause of cataract.

GENTLEMEN,—The subjects I have chosen to bring before you, belong to the operative department of ophthalmic practice, and will embrace the various operations on the eye and its appendages, that are demanded from disease, accident, or malformation.

Ophthalmic surgery has been cultivated from the earliest ages of medicine, and during its progressive development, has numbered among its cultivators some of the greatest ornaments of our Profession, men whose originally powerful minds have been enlarged and heightened by their brilliant attainments.

It would not, however, be consistent with the nature of this short course of lectures, which are intended to be strictly practical, to introduce, however interesting it might be, any historical matter. For this reason, when treating of individual operations, I must avoid mentioning the period of their introduction into practice, and the improvements effected in them from time to time. Should you desire information on any of these points, you must seek it in the various systematic treatises and monographs on ophthalmic subjects that have appeared in England and in other countries.

Little advantage would be expected to accrue, were I merely to give the details of the various operations, without entering into a consideration, or description, of those changes and alterations from normal conditions which make these operations necessary. I shall be careful, however, to keep within proper bounds, and endeavour to be comprehensive and perspicuous, without being too lengthy and uselessly minute. I shall occasionally allude both to the writings and practice of modern authorities, to confirm what I advance to you. Whenever my own experience does not enable me to guide you, I shall gladly adduce that of others, and recommend whatever course I myself should follow.

In connexion with the several subjects, I shall illustrate from the patients so far as the resources of the Hospital will permit, and exhibit whatever drawings I possess, all of which have been taken from my own patients, by Dr. Westmacott, of King's College, whose accuracy and aptness in delineation are well known. The aid of diagrams will be resorted to when they are likely to facilitate description.

It may not be unprofitable to refer briefly to the performance of ophthalmic operations. Comparatively few surgeons undertake them; the cause is easily assigned. Hitherto not many could command the opportunities that are indispensable to produce proficiency. Yet the rapid extension of Ophthalmic Institutions throughout the kingdom, and the daily increasing zeal with which the Medical students and the young Medical Practitioners embrace ophthalmic subjects, induce me to believe that a few years will witness a great change in this respect.

Putting aside those whose total want of manual tact, or great nervousness, disqualifies for any manipulations requiring delicacy, I believe that, with proper training, any surgeon may become a successful operator. Of course there has been, and ever will be, various degrees of excellence in operators, owing to the differences of natural aptitude, and of that derived from diligent study and practice.

All of our best operators in ophthalmic and in general surgery, have devoted much attention and labour to that for which they have been subsequently distinguished. It would, indeed, be singular, were it otherwise. Can it be expected that any one shall do by chance that which demands for its perfection labour and pains? Without due preparation, you must not expect that success will attend your operations, and especially such as involve the globe of the eye. I have seen some sad failures in the hands of those who fancied that nothing however new to them was too difficult to be attempted.

Many are deterred from operating by the much bandied absurdity, that a very large number of eyes must be lost, or rather destroyed, in preliminary attempts. I will show you how to qualify yourselves and falsify that assertion.

Remember that you ought thoroughly to understand the object you desire to accomplish, to contemplate it in all its bearings, and to obtain a certain amount of practice to enable you to execute with accuracy and effect. The head and the fingers must alike be educated. Fortunately, living man need not be the subject of your first essays. The eye of a recently dead subject, forms an excellent substitute. In practising on it, avoid slovenliness; use all the care and precision that should be exercised in life; acquaint yourselves with the nature of the structures you have to deal with, and the amount of resistance they offer to instruments.

You ought frequently to witness the operations of others, and notice the accidents or emergencies that arise, and the best method of meeting, overcoming, or avoiding them. You may often learn much from seeing the performance of a bad operator.

There are yet other conditions that should be complied with. Familiarise your fingers with the living eye, and its appendages, by the various little acts, I can scarcely call them operations, that are required of the Ophthalmic Surgeon in his ordinary daily practice. You thereby accustom yourself to the motions of the globe, and learn how to restrain, or direct them when necessary, to control the resistance offered by the lids, and, not the least important, you are habituated to the restlessness and irritability of patients.

For first operations the young Surgeon should choose those cases that are least likely to offer difficulties.

To proceed satisfactorily with the various peculiarities you will meet with, you must possess tact and self-control, and these can scarcely be acquired without frequent practice. He who operates but seldom, can never be very confident, for, before his next operation arrives, he has lost the experience and advantage of the last.

In no other practical department of surgery is bad operating sooner detected than in the ophthalmic, whether in immediate performance, or in results. Carelessness can never be indulged in by those most practised, without its heavy penalty.

The stand you take as Ophthalmic Surgeons will greatly depend on the success of your operations.

They are the test by which you will be judged Should you operate badly, it matters not how your name may be bolstered up,—in spite of all, you will take but a low position. On the contrary, if your cases turn out well, notwithstanding any difficulties you may have, at first, to surmount, in due time you will obtain the deserved confidence of the Profession and the public.

One of the best operators we have ever had in this Kingdom was, in the first instance, so unsuccessful in his attempts at extracting the cataract, that he was restrained from operating at the Institution to which he was attached for two years, and during that time he was literally confined to the minor operations only. He had the good sense to submit with patience to this decree, and the issue of his patience was, that he became one of our very best operators for cataract. This valuable man was prematurely cut off; but he has left behind him for our example, his patience under temporary eclipse, his unwearied perseverance in overcoming his natural impediments, and his modesty and quiet dignity when great and deserved success crowned his labours and his zeal. What occurred in his case may occur to each of you. To deserve success is much more meritorious than to achieve it. The desert depends on character, energy, and perseverance. The success sometimes depends on adventitious circumstances. Yet we find, in the majority of instances, that desert and success go together; that the latter is, as it were, the natural consequence of the former.

The first subject that I shall enter on, is that of cataract. When you become yourselves experienced, you will agree with me in rejecting the usual division of this disease into the true and spurious, and in confining the word cataract to those changes in the crystalline lens and its capsule, whereby their transparency is destroyed, and in admitting only two sorts, lenticular and capsular. When both of these exist at once, the term capsulo-lenticular is used.

By spurious cataract is meant, the various deposits (for the most part the result o inflammatory action of some portion of the eye), that are seen on the anterior surface of the capsule of the lens. I have invariably observed, that ophthalmic students are much puzzled and confused by these so-called spurious cataracts; for although the appellation "spurious" is used, yet, in combination with cataract, it conveys a wrong idea, besides mystifying and obscuring that which may be rendered easy and plain. Is it not more intelligible, and even more learned, to say (for the words at once convey an idea), that there exists a deposit of lymph on the capsule of the lens, with more or less adhesion of the iris, as the case may be, than to talk of flocculent, trabecular, clotted, or fibrinous cataract, these names being given according to the form of the deposited mass, and the condition of the pupil?

These are also described among the spurious: sanguineous, purulent, and pigmentous cataracts, and these are divided into species. I would advise you not to pay any attention to these names; the practical surgeon neither requires nor uses them; but acquaint yourself with the various morbid conditions of the eye, and you will not have any difficulty, when necessary, in describing them in terms that can be readily understood by any well-educated surgeon. These changes to which I merely alluded are so connected with general diseases of the eye, that a full consideration of them is beyond the scope of my lectures. It is only when they form impediments to operations, or in themselves so far impede and obstruct vision as to demand operation, that I shall include them in my observations.

Although cataract may occur at any period of life, there being no age exempt, from the foetus in utero to the utmost limit of man's existence, it is most commonly seen, and appears more properly to belong, to infancy and advancing years. Besides loss of transparency, the lens and its capsule while opaque exhibit changes in size and alterations in structure. The former may become smaller or larger than in health, softer, or even fluid. The latter may lose all its delicacy of structure, becoming tough and greatly thickened, and, I believe, with that alteration acquires the property of absorbing Associate, then, with cataract many pathological effects.

Inasmuch as these deviations from normal conditions can be satisfactorily recognized, and as your treatment must be adapted to the individuality of the case, it is your duty to learn how to distinguish each one from the other.

As a general rule, whenever you perceive a discoloration posterior to the iris, avail yourself of the advantage to be derived from a dilated pupil. Much doubt of the nature of a cataract may thereby be dissipated. Again, the use of belladonna, or its more elegant preparation atrophine, may often render great assistance to diagnosis in cases of imperfect vision that do not show any opacity in the ordinary state of the pupil; for, as I shall have to show more in detail when I proceed, the crystalline lens may be opaque in its circumference, and not in its centre. Then there is the value of negative evidence in observing a clear pupil.

The question must have suggested itself to you what is the cause of cataract?—and, naturally enough, the same interrogatory is often put by patients. I cannot, in a word, supply you with an answer; the subject requires a little consideration.

The commonest form of cataract, the lenticular, occurring at the middle period of life and in the aged, cannot be accounted for. Pathology and physiology afford us no elucidation of the fact. All the theories that have been advanced are untenable. The same, too, must be said of the majority of lenticular cataracts that occur in early life.

It must be remarked, however, that we meet with cataract less rarely in an uncomplicated state, existing as an affection by itself, than co existing with unhealthiness in other parts of the eye; and often this combination cannot be detected before the cataract is removed; yet we are not thereby enlightened as to its cause. Sometimes we have unequivocal proof of the capsular as well as the lenticular form, depending on inflammatory action, originally invading other structures of the eye, either in an active form, or slowly and insidiously, and ultimately involving the lens and capsule, and producing opacity. Theoretically, one is inclined always to attribute capsular cataract to inflammation, from the change the capsule undergoes, which is analogous to that in other parts of the body usually considered to have such an origin.

Traumatic cataract is generally accompanied with more or less inflammation of some of the other textures of the eye, but not necessarily so, for aught that we can appreciate. It may follow slight concussion of the eye, without any apparent lesion.

Mr. Lawrence says, that "soft capsulo-lenticular cataracts often form in consequence of congestion in the organ." Dr. Mackenzie writes to the same effect: "Inflammation is, in some cases, the proximate cause, not merely of true, but even of spurious cataracts." Yet, as the former author observes, "we cannot generalise the observation, and say, that inflammation is invariably the cause of cataract."

In the Number of the *Medical Times* for February 26, 1848, I published a case of capsulo-lenticular cataract, on which I operated, that had a well-marked inflammatory origin.

I have seen a few instances, in young persons, of what I suppose I may call lentitis. With the existence of uneasiness in the eye, the lens became opaque in a few days, the capsule remaining unimpaired.

It is astonishing how quickly bodies of such low organization as the lens and capsule, can become opaque. A lad, who received a blow in the eye with a stick, presented himself twelve hours after the accident; capsulo-lenticular cataract was formed. Ordinarily, some days elapse before opacity is perfected.

Circumstances usually recounted as the remote or predisposing causes, are so vague, I may almost say absurd, as to forbid any notice of them, except that of hereditary tendency; and here the ancestral influence may be very palpable, but, fortunately, is very rare. I shall conclude my lecture with one of the cases that have come under my own observation. The patient was aged 23, with lenticular cataract in both eyes. Her three sisters, maternal aunt and uncle, and maternal grandfather, had been similarly affected.

ORIGINAL CONTRIBUTIONS.

REMARKS ON VENEREAL DISEASE.

By F. C. SKEY, Esq., F.R.S.

In my last paper, I expressed my opinion on the nature of the venereal disease as regards its possible, and indeed, its frequent, not to say common, mode of propagation. I gave a slight sketch of the evidence on which my opinion was confirmed. It was founded on observation alone. I did not affect an isolated singularity, but I did claim to myself the merit, *quantum valeat*, of daring public opinion by the advocacy of a doctrine I believe to be true. It appears to me, that, supposing these opinions to be correct, their adoption must compel some modification of the treatment employed by the majority of the Profession for the cure of primary venereal sores; for, if I can succeed in simplifying the pathology, the hope that I may influence their treatment also, would not be an unreasonable one. With this view, I proceed to strengthen and entrench my position by additional evidence, pointing to the important fact, that venereal disease is capable of propagation by the intercourse of two persons, neither of whom, singly, shall be the subject of disease in any form. I am told, that I have adopted my views on "insufficient evidence." I dare say I have,—insufficient enough to influence the minds of those who have reached the final goal of their belief. "Really, Sir," says one friend, himself an Author on this subject, "we did not expect such extreme doctrines to have emanated from St. Bartholomew's Hospital." Now, I have a great respect for the traditionary excellence of St. Bartholomew's Hospital, and for its medical staff, past and present, Pott and Abernethy included; but I have a much higher respect for truth, and I do not know that I have not a remote pleasure, even extending to the possession of a small spice of malice, in the exposure of error.

In my former paper, I quoted authority in favour of the doctrine I endeavoured to promulgate. I did not pretend to quote the *opinions* of these Authors, but I merely referred to such passages in their writings as appear to me to point to the one and only deduction, viz., the frequent spontaneous origin of venereal disease; but I prefer to this form of evidence, however strong, that of my own senses. I prefer that of experience and observation. I would say to every man not indisposed by prejudice, and whose opinions on the subject of venereal disease are not stereotyped on his mind as final, examine and observe, scrutinize the circle of your own practice, public and private, but especially the latter. In addition to the authorities I last quoted, for in obedience to the world I ranged them in advance, placing *reason* at a respectable distance in the rear,—I shall now call the name of John Hunter into the witness-box, and we will see, on cross-examination, what evidence we can extract from him. In the first place, I find no evidence in his works in *direct opposition* to the doctrine of spontaneous origin, plenty to infer his adoption of the general views of the Profession of his time, viz., that it is a disease communicable from one person to another. This, however, is undisputed. In his chapter on the venereal poison, I find the following:—

"In women the inflammation *is frequently* very slight, and often there is not *the least sign* of it, for they have been known to affect men, though they themselves have had no symptoms of inflammation, or *of disease in any form*. Therefore, the inflammation and suppuration, when present," (in the male I presume,) "are only attendants on the peculiar mode of action, the degree in which they take place *depending more on the nature of the constitution than on that of the poison*." (The italics are my own.) Mr. Hunter here declares his belief

that a woman, who has *no disease in any form*, can generate disease, in the nature of "inflammation and suppuration."

If this be not gonorrhœa, what is it? What is a gonorrhœa but inflammation and suppuration? Who can distinguish between the inflammation and suppuration, the result of intercourse with a woman who has "no disease in any form," and the inflammation and suppuration got from an unknown source, whether clean or unclean, and to which we unhesitatingly apply the term gonorrhœa, *because* we infer it to be the product of another gonorrhœa? Ardor urinæ, chordee, inguinal suppuration, orchitis, are as frequent attendants on one as on the other. They run the same course, and are amenable to the same treatment. In short, they are one and the same disease.

That the constitution exercises an important influence in increasing and lessening the intensity of this disease, may be inferred from the fact, that its activity is diminished as age advances. It is the disease of early, not of confirmed, and still less of advanced, manhood. The later its appearance in life, the more amenable is it to treatment.

On the chapter on Gonorrhœa, Mr. Hunter says:—"Mr. and Mrs. —— have been married twenty years. She has for many years been troubled with fluor albus. When he has connexion with her at such times, it has generally, though not always, produced an excoriation of the glands and prepuce, and a considerable discharge from the urethra, attended with slight pain. These symptoms commonly take a considerable time before they go off, whether treated as a gonorrhœa, or as a weakness. Is this a new poison? and does it go no further because the connexion takes place between two? What would be the consequence, if she were to have connexion with other men, and these with other women?"

To these questions I will presume to give an answer. If the above lady had had connexion with a young and healthy person, he might have carried away as virulent a gonorrhœa as ever required medical treatment; and had the experiment been conducted with common ingenuity, he might have infected the mistresses of the whole camp, pioneers and all.

The very question raised by Mr. Hunter infers the leaning of his own mind towards the belief that gonorrhœa may be engendered from leucorrhœa, itself the product of simple irritation.

The evidence applied to the spontaneous origin of venereal sores, at least from one sore, is equally conclusive; and if one, why not all. The sore to which I allude is, of all venereal sores, the most common, and it holds a singular relationship to gonorrhœa, arising probably from the same poison. I am in the habit of designating it as "the common sore."

It is named by Mr. Evans, the common venerola—a name adopted by Mr. Welbank, than whom I know no higher authority on venereal disease at the present day. It commences at an average of three days after connexion, in the form of a pustule, which matures and bursts. It then becomes a sore, and progresses in size till it reaches that of the little finger nail, or less. Sometimes, however, it increases, to that of the thumb nail. This ulcerative stage occupies from two to four weeks. The physical characters of this common sore, at this stage, depend on its situation. It may form on the glans, on the fossa, on the prepuce, or on the body of the penis. It is rare that it cannot be distinguished by ordinary observation. It is characterised by *an elevated ridge surrounding it*, within which the sore appears to be depressed below the general level. On the body of the penis, that is to say, when seated in common integument, the ridge is strongly marked, and constitutes a very palpable feature, and it then bears a remarkable resemblance to the ulcerated patches of Peyer's glands in fever. In form the sore may be round, but is more commonly irregular. As it advances, granulations form on its base, which, when matured, rise up to a higher level than the surrounding skin. The walls are absorbed, the granulations shrink, and the cicatrising process terminates the affair. This is the course of a well marked common venereal sore; but neither the walls nor the elevated granulations are the essential, though the frequent, and even the general concomitants. This is the common sore; so common, that Mr. Evans declares it to prevail in nine out of every ten examples of the disease.

I have spoken of its probable identity with the poison of gonorrhœa. The grounds of that opinion are these:—1st. That it runs its course in about the same term; 2nd. That it is frequently observed in small clusters, around the prepuce, in cases of protracted gonorrhœa; 3rd. That, like gonorrhœa, it is often of spontaneous origin; and 4th. That when time is allowed it to progress, unmolested by interference, it reaches its curative stage without requiring the assistance of any other surgeon than nature.

It has another very important feature, and to which, out of many thousand examples that have come within the range of my observation, and the large proportion of which have been under my treatment, I have never known an exception,—viz., *that it never produces a constitutional symptom of any kind, neither sore throat, nor eruption, nor local pain.*

I conceive that I should do no small service could I establish the truth of this most important fact,—viz., that the common sore, prevailing in nine out of ten cases, or say five out of six, runs its own career, through ulcerative, granular, and cicatrising stages, in six weeks, in a regular and steady progression; that its progress, except the very last stage, is accelerated by no treatment, local or constitutional; and that it leaves no trace or mark on the constitution to raise a passing regret that mercury had not been employed.

I will venture to affirm, of my own knowledge of his sore, with which I have made acquaintance for a great many years, and have seen some thousands of examples, that out of the whole range of circle of disease, there is none more abused, and more discreditably treated. The treatment really required is purely negative. By an occasional pill of compound rhubarb, and spermaceti ointment locally, all its medical wants are fully supplied; anything beyond this, is obtrusive and injurious. For many years I treated it with the following antiphlogistic agent, and, among the poorer classes of the world, I do not know a better, *if given in sufficiently large doses!*

℞. Micæ panis, gr. v.; aquæ puræ qs.; M. ft. pil.; omni nocte sumenda.

Most practitioners, who don't know the characters I have above sketched of this sore, treat it with mercury. It is often called the true Hunterian chancre, although totally destitute of hardness every stage, if let alone; but, let its progress be disturbed by the hand of science; torture it by remedies; stimulate it by unguents; irritate it by escharotics; then it will assume a new and important feature, viz, its base will become hard. I have elsewhere drawn a distinction between the hardness of thickening, and the hardness of induration; but, I am not so absurd as to imagine the Profession to read books on venereal disease, I will venture briefly to repeat my observations. The terms are arbitrarily employed to express different degrees of the same quality. Many forms of ulcer, as they become chronic, become also hard, and the common venereal sore is one of them; but the hardness is moderate, not extreme. Moreover, it is confined to the parts immediately contiguous to the sore, and not to the circumjacent tissue. The true syphilitic chancre appears as though set in a mould, or base, of cartilaginous induration. But there remains a further distinction, yet more clear and characteristic of the two diseases, viz., that the thickening of the chronic form of common sore is of late growth in the progress of the sore, whatever its locality; whereas the induration of true syphilis is coeval with the sore, and even precedes it. To the common sore it is incidental, while it constitutes the main feature of syphilis. If the observance of the characters of the sore be backed by its history, its nature will be generally determined without difficulty. Syphilitic disease rarely appears within ten days after intercourse, the common sore in three or four. Syphilitic disease is remarkably destitute of pain in all its stages. The nucleus of the disease resides in the induration, not in the sore, which is incidental to the induration. Induration alone, without a sore, will cover the skin with eruption.

The greatest evil attendant on the thickening of the common sore, consists in its mechanical influence in arresting the healing process. There is really no greater necessity nor excuse for mercury, than though thickening were absent. But the disease is greatly protracted, and may remain stationary for weeks, or even months. If the sore be pared round the edges with scissors, or destroyed with caustic potash, it will heal.

There is only one stage of this common sore that justifies intervention, by the application of bluestone to the granulations, where they rise to the level of the edge, or above the surrounding surface, supposing the raised margin to be absent.

Supposing the variety of venereal sores to depend on the difference in the poison producing them, that would prove a highly interesting subject of inquiry, which would establish the existence of the distinct forms consequent on each other on the same person; *i. e.*, the poison of the common, according to general belief, should invariable produce the common sore; phagedenic poison, a phagedenic sore; and syphilitic poison, the syphilitic sore. But I cannot call to my recollection any single instance in which I have seen two different forms of sore on the same individual. I have seen a succession of common sores, and a succession of phagedenic sores; but I have not, to the best of my recollection, ever treated a common sore in the person of a patient whom I have known to have had phagedenic disease previously, or *vice versa*.

If this subject were thoroughly investigated, and if the result proved that every constitution had its own sore, and that the occasional existence of two forms of sore at different times in the same individual, formed but an exception to the rule, should we not refer the nature of the sore to the constitution of its possessor, and not to the specific poison of the woman supposed to have engendered it. Yet the doctrine is not an improbable or an unreasonable one. I believe, that of three men having intercourse with the same woman, one shall contract the common sore, a second a phagedenic sore, and the third a gonorrhœa. Evidence to this effect is given in Mr. Evans's work, and I have no doubt of its truth.

Grosvenor-street, June 22.

MEDICAL SCHOOLS AND UNIVERSITY TOWNS OF GERMANY.

By Dr. BUSHNAN.

Before continuing my account of the Medical Schools and University Towns of Germany,—an account which the disturbed state of that country and the many collegiate changes that riot and rebellion, with their attending ruin, have brought with them, have sadly interrupted—I propose, in the present and succeeding numbers of the *Medical Times*, to say a few words upon the Profession and system of medical education in Prussia,—a system which, with some very slight modification, is adopted in the minor states of the Germanic Confederation as well as in Saxony and the Saxon Duchies, Wirtemburg, Hanover, Electoral and Grand-ducal Hesse and Baden. Bavaria and Austria have their own systems. My task is not one of great difficulty, since the Report of Hoefer to the French Minister of Public Instruction, upon the same subject, will, in great measure, form the basis of the present account.

The system of government, then, of the Medical Profession in Prussia, and in the states I have named, is purely hierarchal. As its seems to me, it can most appropriately be described at this time, and in these days of medical reform and agitation; when in England the hands of the great mass of the Profession appear raised to knock down that which they cannot clutch, to level institutions to which they do not belong, even when by complying with established rules, they may be received into

their bosoms, and, when there, lend their help and aid to purify and improve them, and adapt them to the exigencies of modern times and the general spread of knowledge. But the habit of the present day is to raise up new altars—too often, to an unknown God —and to form new corporations, new associations, among which men would worship, but in which they themselves would be one of the worshipped; but of the form and mode of which none can agree, each having his own undefined and vague idea. And from the mass of opinions that have been offered, and the hecatombs of advice that have been sacrificed, we can only gather that each man wishes to be first, to have his slice of the cake, and his own particular finger in the pie. As it seems to me, the existing Institutions, if properly remodelled and new chartered would be amply sufficient for every necessity. It is unreasonable to say there shall be no grades in the Profession, for there they must exist, as in every other department of life; but it is quite fair, and very necessary, that as few impediments as possible should be placed in the way of men rising in the scale, and arriving at the highest position. But so long—let the course of education and the nature of examination be what they may—so long as the public think Dr. A a wiser man than Dr. B, and therefore call him to consultation; or fancies Mr. C is cleverer than Mr. D, so long must grades exist, if not of rank, at least of reputation. In professing to give a survey of the Prussian system of medical government, I do so, as much with the object of explaining their mode of arranging these matters, in a country which is altogether of a military character, as with the avowed intention of selecting those points for especial consideration which I humbly conceive might be transferred with advantage to our own Colleges, and infused generally into the leaven of our medical diathesis,—if such a term be not uncongenial to British ears. I am very far from being a blind admirer of the German system; indeed I hold that, in the present state of our knowledge, what are named *systems* are merely rude attempts at the ideal of perfection in the mind of man; and, again, in some points of view, they are often miserable abortions. There is this, however, to observe, that the whole Medical Profession in Germany is united in one body; one system connects Professors, Teachers, and Practitioners, different as are their walks and grades, into one harmonious and compact union, or rather unity of purpose — even from the highest Councillor of the State, who presides over the meetings, or assemblage of the medical authorities, to the humblest attendant duly instructed by the education he has gone through to perform adequately the offices of his station—not an unimportant one—to watch with assiduity and care the couch of the sick.

How widely different is the system followed in the British Isle? What an incongruous mass of interests embroiled in ceaseless quarrels and jugglings with each other! The College of Physicians against the Apothecaries' Company; the Apothecaries' Company against the College of Physicians. The College of Surgeons aloof from both, yet indirectly obedient to the call of the one or the other, as interest may direct. One system of education north of the Tweed, another south, and a third in the sister isle; and all enacted and enforced by penal statutes. No wonder quackery has taken so strong a hold in the British Isles.

Yet, with all these differences, we have still some noble institutions, and some noble "Fellows" presiding over their destinies.

It is true, however, that there are various deficiencies to be supplied, imperfections to be amended, superfluities of the olden time to be pruned, and modifications which the expanded and hourly expanding nature of the great and *one* science of the healing art imperiously demand to be introduced, in order to satisfy the more enlarged demands of a generally more enlightened professional body, and adapt it to the spirit and genius of the times.

There is one circumstance in German medical polity to which I wish particularly to call attention. Whatever may be the kinds of state doctors, civil doctors, military doctors, surgeons, and other practitioners, invariably in Germany the preparation and sale of medicines is a distinctly separated and isolated department of the Profession. I say distinct, because there is a class of men who devote themselves specially to that duty, trade, or profession as it chances to be termed; and *isolated*, I further add, because the persons so engaged are restricted and bound by heavy penalties solely to that pursuit, and never are permitted to interfere with practice, be it medical, surgical, or obstetric. In this simple fact I have expressed one of the grand features of the difference between British practice and the usage followed on the Continent; and if I do not apprehend erroneously, it is the source of a great part of the evil in our country—the canker-worm of our profession. Through the practice of selling drugs by those who give advice, the public has been insensibly driven to a want of confidence in those to whom they naturally look up in the hour of trouble; and thus doubting their honesty, they are urged to seek refuge in the impudent assurances of the nostrum-monger. (a)

As, then, I have not yet given up hopes that our medical corporation statutes may yet be re modelled, it will not be time misspent to take a summary view of a system of medical organisation, which, whatever may be its faults, has, at least, the merit of a unity of purpose which may not inappropriately be held as the nucleus of an amended and more liberal organisation of ourselves. With the *aperçu general* which Dr. Hoefer presents in his Report, I think every member of the Medical Profession will feel desirous to be acquainted, since it enunciates a complete system of medical organization which has been found to work well in a country so large and populous as Germany, and among those to whom we ourselves are indebted for some of the most valuable information and knowledge we possess.

In concluding this, my first or introductory communication upon the subject, I may observe that I shall first describe an official class of medical men, denominated public medical functionaries. These are totally distinct from all other in their duties. France offers nothing similar to them, and, among us, their only type is to be found in that nondescript anomaly the Board of Health.

I shall next describe the system of study and medical instruction, and the conditions under which degrees are granted. The different grades of practitioners, civil as well as military, will next engage my attention.

With the exception of the Bavarian, Prussia stands pre-eminent as a model for all the secondary states of the Germanic confederation. Accordingly, an account of the medical organization of that kingdom and of Bavaria is sufficient to convey a correct and full impression of the *status* of the Profession in Germany. Such differences or peculiarities as prevail in the other States of the Confederation, I need only briefly notice in order to complete the sketch. I may add, that in Germany, as elsewhere, men are dissatisfied with what they possess, and are unable to agree as to what they require.

(a) I remember being called in consultation to a case of that very rare disease, general emphysema after fever. "All medicine must be discontinued," I said, "and reliance entirely placed upon wine." "That is quite impossible," replied the surgeon in general attendance; "I am only paid by my medicines, and I cannot come several miles without prescribing three eighteenpenny draughts, a three-and-sixpenny mixture, and a powder daily." Every physician in consulting practice has met with similar occurrences.

REMARKS ON AN OCULAR SPECTRUM, INDICATING A SLIGHT OBLIQUITY IN THE LENS WITH RESPECT TO THE AXIS OF THE EYEBALL.

By J. D. MACDONALD, Esq., Member of the Royal College of Surgeons.

It is well known, that when a blackened card, with a small perforation, is brought close to the eye, the aperture will appear very much magnified; and, also, that whatever be its figure, a circular form will be perceived. This is, of course, easily explained when we consider the great divergence of the rays passing through the aperture in the card, and the insufficient powers of the eye to affect their concentration upon the retina, so that a shadow of the iris falls upon it, the pupil modelling (so to speak) the mass of rays in their course, and thus causing them to form a circular spectrum of considerable size. The writer, however, is not aware that any physiologist has observed the outer, or temporal border of such a spectrum to be somewhat defective, or paired off, while at the same time it is much brighter and better defined than the inner. The appearance noticed is made very striking when a series of perforations are employed as represented by the dots . . . . In this case, whichever eye may be used, the bright external margin of each circle will be clearly seen to overlap (as it were) the weak internal one of that which lies next to it, and the whole resembles much, in effect, a string of pearls. By looking through the perforations alternately with the right and left eye, the overlapping of the circles will be also perceived to change from right to left.

In explanation of this phenomenon, it occurred to the writer that the crystalline lens must hold a slightly oblique position, with reference to the axis of the eye-globe, or the plane of the iris; for, such a supposition, the whole matter is very easily accounted for.

If the rays of light from a candle be collected by means of a common lens, and thrown upon a screen before their complete convergence, as long as the planes of the lens and screen are parallel, and both perpendicular to the central rays, a circular spectrum results equally bright all round its margin; but, if the position of the lens be in the smallest degree oblique, that part of the spectrum formed by the light passing through the border of the lens most distant from the screen will, in consequence of the great convergence of the rays, be rendered more brilliant than the rest, and also more contracted or pared off. In short, the entire effect is exactly similar to that noticed above, as formed in the eye itself; and like that case also, the beauty of the illustration now under consideration is much enhanced, by employing a row of luminaries placed closed together, when the bright border of each circle will be found to overlap or obliterate the weak one of that which lies next it.

That the position that the writer has assumed is correct, is further indicated by the symmetry of the effect as occurring in both eyes, and by the anatomical fact, that the ciliary processes on the inner side of the lens are somewhat shorter than those on the outer, which arrangement seems to be intended to bring the lens more directly in front of the spot of Sømmering, which end must also be partly answered by the oblique position of the lens alluded to; for it is plain, that as (by some mental operation, but little understood by Physiologists) the images of objects formed on the retina in a certain position are represented to the mind as if reversed, it follows that the bright side of the circles painted on the nerve must be situated towards its inner side, an opposite condition to the appearance observed, and which is produced by the inner border of the lens lying more distant from the retina, or nearer to the iris than the outer; such an arrangement having the effect of throwing of the whole mass of rays a little inward and also effecting their concentration towards the inner side first, which may be required in certain positions of the eye-ball. It is probable that the ciliary muscle, so beautifully described by Mr. Bowman, has a special operation in altering the plane of the lens, causing obliquity in different directions, as well as the other functions ascribable to it. (a) There is one more supposition which may be advanced to account for the phenomenon above described, viz.,—that the substance of the lens is of

(a) Such as altering the distance between the retina and lens, drawing upon the anterior wall of the capsule, &c., so as to adapt the eye to vision at different distances by combining the effects of focusing and varying the convening force of the crystaline humour.

greater density at its inner than at its outer part whereby it brings the rays passing through the former to a focus somewhat sooner than those transmitted by the latter; but this condition would obviously render the lens defective in its operation and is, therefore, not likely to exist.

ON SCARLATINA.

By J. W. TRIPE, M.D., M.R.C.S., and L.A.C., London.

(Continued from Vol. XIX., page 672.)

MARCH.

The mean temperature of the air for these months of March was 42°·8; so that if the air had been saturated with moisture it would have contained 3·39 grains of aqueous vapour in a cubic foot; but as the mean dew-point temperature was 5°·6 below the temperature of the air, the average number of grains may be calculated at 2·81 in each cubic foot. The mean humidity was above ·853 four times, and below it five times; the four former presenting a plus of comparative mortality thrice and a minus once; the five latter a plus of mortality twice and a minus thrice. The mean comparative mortality for these months of March, in which the atmosphere contained an excess of moisture was 99; whilst for those months in which the humidity was minus ·853. the mortality was only 83. This forms a remarkable exception to the otherwise invariable rule, as will be shown hereafter; viz., that a plus of moisture is ordinarily accompanied by a minus of mortality. We can, however, draw no other conclusion than that a plus of humidity appears in March to induce an increase in the mortality from scarlatina; they were certainly coincident.

APRIL.

Although the atmosphere was not so highly saturated with moisture in this as in the last month, yet the actual quantity contained in it, at Greenwich, was greater than in March. Thus, the mean temperature of the air was 47°.2, which, if saturated, would have contained 3·90 grains of aqueous vapour in a cubic foot; but, as the mean dew-point was 41°·1, being 6°·1 below the mean temperature of the air, the quantity actually contained was only 3·14 grains. Assuming, then, that the mean humidity of the atmosphere for April is ·809, we find it to be in excess in four, and minus in five months: in the four former the comparative mortality was above the average twice, and below it twice; in the five latter the mortality was plus four times, and minus once. The mean comparative number of deaths for the months in which the humidity was in excess was 83, and for those months in which the humidity was minus, it reached 93. We may, therefore, say, that the months of April, in which the humidity exceeded ·809, were those in which the mortality from scarlatina was in excess; in other words, that a humidity above ·809 will have a tendency to diminish, whilst a humidity below this sum will have a tendency to increase the number of deaths from scarlatina.

MAY.

The mean temperature for May during these nine years was 51°·8; so that if the air had been saturated with moisture, each cubic foot would have contained 4·99 grains; but as the dew point temperature was 48°·2, the quantity actually held in a foot was 4·01 grains: or the same conclusion may be arrived at by comparing the mean temperature and the mean humidity, ·801 In six of these months the mean humidity was above, and in three it was below the average; in the six former the comparative mortality was five times plus, and once minus; in the three latter the mortality was twice above and once below the mean. The mean comparative number of deaths for the months in which the humidity was above the mean was 108, and for those which were below the mean 129. From these data we may assume that an excess in the humidity of the atmosphere is more favourable to health as regards the disease under consideration, than an unusually dry state of the air.

JUNE.

As the mean temperature of the air for this month was 60°·2, 5·91 grains of aqueous vapour would have been contained in a cubic foot had the atmosphere been saturated with it (which would have been represented by 1·000); but as the mean humidity was only ·784, the quantity actually held in it amounted to 4·57 grains only in each cubic foot Three of the above nine months of June presented an excess of moisture, with a plus of comparative mortality in two of the three, and a minus in one and six of the months had an unusually low degree of humidity, the comparative mortality being three times plus, and three times minus. The mean of the comparative mortality for the months which had a plus of humidity was 106, and for those months which presented a low degree of humidity it was 137. It is evident that an excess of humidity in June was coincident with a small increase in the mortality of scarlatina above that of the preceding month (May), whilst a low degree of humidity was attended with a very large increase in the mortality

JULY.

The average of the mean temperature during these nine months of July has been shown to be 61°·5, at which temperature each cubic foot of air would hold 6·15 grains of aqueous vapour if saturated, but as the mean degree of humidity was only ·800 the quantity actually contained in a cubic foot was 4·83 grains. In four of these nine months, the mean degree of humidity was above the average, the comparative mortality being once plus and three times minus in these four months; in five months the humidity was minus the mean, with a minus of comparative mortality twice, and a plus thrice. The mean comparative number of deaths in those months which presented a plus of humidity were 112; in those months which had a minus of humidity, 121. An excess of moisture was co-existent in July with a rather small increase in the mortality from scarlatina, whilst a small amount of moisture in the air was attended with a larger increase in the number of deaths.

AUGUST.

The quantity of aqueous vapour which a cubic foot of air would have contained, had the atmosphere been saturated with moisture, would have been 6.12 grains; but it was not saturated, as each cubic foot contained only 5·00 grains. The mean degree of humidity was above the average in five, and below it in four months: the five former having a plus of comparative mortality three times and a minus twice; the four latter had a plus and a minus of mortality twice respectively. The mean of the comparative mortality for the months of August, in which the humidity was in excess, is 109; and in those in which it was below the mean, 105. The evidence in favour of any great effect produced by variations in the degree of humidity of the atmosphere is less marked in this than almost in any other month; but the balance is in favour of a moist being less fatal than a dry atmosphere.

SEPTEMBER.

The quantity of aqueous vapour contained in a cubic foot of air, taking a mean for the nine months, was 4·59 grains; the quantity which the atmosphere would have contained had it been saturated would have been 5·32 grains. The mean degree of the humidity of the atmosphere was plus the average, ·861 in five months, the comparative mortality for these months being larger than usual in one only, and smaller in four; it was below the average in four months, the mortality being plus twice and minus twice. The mean comparative number of deaths in the months presenting a plus of humidity was 114, and for the months having a minus it was 140. We may, therefore, conclude, that a September having an usually high degree of humidity is more likely to be healthy as regards scarlatina than one having a low degree of humidity.

OCTOBER.

Had the atmosphere been completely saturated—1·000—with moisture, the quantity of aqueous vapour which it would have contained in a cubic foot would have amounted to 4·23 grains, but as the air was not saturated, the mean degree of humidity being ·888, and the temperature of the dew point 45·8, whilst that of the air was 49°.6, the quantity actually in a cubic foot was 3·73 grains. The degree of humidity was in excess in five and minus in four months; in the five former the comparative mortality was plus once, and minus four times; in the four latter—the minus—the mortality was above the mean twice, and below it twice. The mean comparative number of deaths for the months in which the degree of humidity was plus amounted to 120, and for those in which it was minus to 121. The amount of moisture in the air appears to exercise but little influence on the mortality from scarlatina in the months of October; the greatest number of deaths, however, happened in the dry months.

NOVEMBER.

As the mean temperature of the air for this month was 44°·6 Fahr., during these nine years, each cubic foot of air, if saturated with moisture, would have contained 3·59 grains of aqueous vapour, but calculating it from the difference between the temperature of the air and the temperature of the dew-point, we find that the mean amount was 3·18 grains in each foot. In one of the months the mean degree of humidity was the same as the average, in three it was in excess, and in five minus. In the three in which it was plus, the comparative mortality was once plus and twice minus the average; and in the five in which the humidity was less than the mean, the mortality was in excess three times, and below the average twice. The mean of the comparative number of deaths for the months in which the humidity was in excess was 85, and for those in which it was minus the mean number of deaths was 99. An excess of humidity in November seems to assist in diminishing the mortality from scarlatina during this month.

DECEMBER.

The temperature of the air for this month having been shown to have had a mean of 40°·0 in these years, (1840-48,) the quantity of aqueous vapour that would have been contained in each cubic foot of air would have amounted to 3·09 grains had it been saturated; but as the mean of the dew point temperature was 3°·4 below the air temperature, it would have contained only about 2·82 grains. The mean humidity was above the average in four of these months; the comparative mortality being plus twice and minus twice; the humidity was five times less than usual, the comparative mortality being twice in excess, and three times less than the average. The mean comparative number of deaths was the same for both, viz., 77. There is not, therefore, evidence to show that the mortality from scarlatina is influenced in this month by the extent to which the air is saturated with moisture.

We can scarcely help being struck with the great uniformity observed between the increase or decrease in the number of deaths from this disease, and the greater or less degree of hygrometrical saturation of the atmosphere; for, with the exception of December, when the comparative mortality was the same for the months in which the degree of humidity was plus, and for those in which it was minus; and, in March, when the mortality was in excess in the months in which the humidity was also in excess, the mortality was less in those months in which the degree of humidity was above the mean.

We ought next to proceed to consider the absolute amount of moisture contained in the air, as indicated by the elastic force of vapour, in conjunction with the mean temperature, dividing the 108 months into four divisions or quarters, and subdividing them into the hot and humid, the hot and dry, the cold and humid, and the cold and dry, and contrasting each of these with the comparative mortality for the month. But this would occupy too much space, and must therefore be omitted, and we shall therefore pass on, to very briefly treat of the influence exercised by variations in the electrical conditions of the atmosphere.

[To be Continued.]

OBSERVATIONS ON WORMS IN THE HUMAN SUBJECT.

By L. F. CRUMMEY, Esq., Stokesley, Yorkshire.

Amongst the more ordinary—but not the least important—of human diseases, occurs that of intestinal worms.

The following observations are the result of long and attentive inquiry:—

The usual varieties of worms which infest the intestinal canal, are the three kinds described by authors as tænia, lumbricus, and ascaris. Although instances occur of the two former varieties requiring medical intervention, yet the ascaris, or *grub worm*, more frequently prejudices health, and demands the aid of medicine. The tænia and lumbricus generally inhabit the smaller intestines whilst the rectum is the common abode of the ascaris. I have never known the tape, or the earth-worm, leave the body but by the mouth or anus whilst the ascaris, not unfrequently makes its exit at the ears, eyelids, and vaginal orifice, as well as the anus; but I never knew it escape by the mouth. The natural habitat of every species of intestinal worm appears to be the mucous secretions; and upon these, together with the accidental contents of the bowels, they feed. Worms are decidedly hereditary. I have known several instances of lumbrici and ascarides in infants, at the breast, but not of tænia. Worms prevail in certain families at certain periods of life; after which they decline, or, at all events, their presence is less obvious. They are directly influenced by the spring and autumn changes in nature, and also by the changes of the moon. At or about the period of the full moon their greatest activity is observed; and at this time medicine has the greatest effect upon them. In the cases of two children, aged nine and twelve years, who were closely watched during the whole of 1847, there occurred a remarkable accession of all the symptoms during the latter part of the moon's filling; and at these times the greatest number of worms came away. In a boy, aged thirteen, who had been subject to epileptic fits for upwards of five years, it was observed that the fits were considerably aggravated at the full and change of the moon, which was attributed to the lunar influence upon epilepsy. He was not supposed to suffer from worms. Subsequently it was ascertained that he was the subject of ascarides; and turpentine was administered; the expulsion of an incredible number of worms was the result. The remedy was repeated at intervals of two or three days, for the space of three weeks, when the worm ceased to be expelled, nor did any indication of its presence remain. The turpentine was discontinued. He never had an epileptic fit afterwards. The generation and propagation of intestinal worms remain involved in great obscurity. In the horse, much appears to depend upon herbage; and different varieties of worms prevail in different localities. [Mr. W. Barker, veterinary surgeon of this place, has in his possession a very remarkable variety of the entozoa, taken some time ago from the cæcum of a horse, which died from other causes; and which has been known to occur only on a certain farm in the neighbourhood of Stokesley.] In the human subject I am quite satisfied that the generation of worms does not depend upon peculiarity of food, &c. I have found them equally amongst children of the poor, and those of the rich; in cases, where no regard was paid to the nature of the diet, as well as those where the most scrupulous attention prevailed. The only liability which I have observed, is where the diet has been almost exclusively animal. In the families of butchers, worms are very frequently found; but in these cases a strong hereditary predisposition is commonly noticed. That the generation of many varieties of intestinal worms in the horse depends upon the insect tribe; that the ova are deposited upon the skin of the animal, and conveyed from thence into the intestinal canal, and there undergo a species of incubation, I could never be induced to believe; for I have frequently observed the same kind of worm where the animal was stable-kept the whole year round; and, further, we find the same variety in the dog, and cat, and also in the human subject. There appears to me to exist in certain habits, in man and in the lower animals, a peculiar tendency to generate worms, and which depends upon circumstances over which we have little or no control. The first stage in which I have ever been able to recognize intestinal worms, is that of the *worm bag;* these mucous pouches seem to be the habitation of the animal for a certain period of its existence; after which it is found in an independent and separate state. The peculiar envelope, to which the common people have given the name of *worm bag*, is found to vary in form, size, and structure. When floating in the evacuations, they resemble irregular-sized pieces of jelly, or slime, adhering to the surrounding matter, but capable of ready and perfect separation. They are, in certain stages, extremely tenacious, and resist considerable pressure. When torn, or cut open, they appear to the naked eye to be filled with small white thread ends, from half a line to two lines in length. Under the microscope, they are revealed as perfect animals; and when exposed to the action of heat, or diluted oil of turpentine, their motions are distinctly perceptible.

Their appearance and the nature of their contents are perfectly alike in the human subject, and in the dog and cat.

It is the observance of these mucous bags in the evacuations which constitutes the only infallible indication of the presence of worms in the intestines when the perfect animal is not known to come away. In one remarkable and fatal case of ascarides which occurred in an adult at South Stockton during 1848 the existence of intestinal worms was never suspected, although the symptoms had continued upwards of six months, until *worm-bags* were detected in the evacuations; nor would the relations believe the disease to be worms, until the opening of the bags revealed their contents. The oil of turpentine was administered, both *per annum* and by the mouth, which had the effect of bringing away an enormous number of worms, in various stages of development, and procuring a marked relief to all the more urgent symptoms. Although in a very unfavourable condition, this patient rallied perceptibly after every dose of turpentine. Eventually, however, he sank. A very intelligent little girl, aged nine years, had been subject for upwards of eighteen months to very peculiar nervous phenomena, sometimes of an hysterical, at others, of a cataleptic character. No method of treatment afforded any decided relief. An examination of the evacuations after purgation revealed the presence of worm-bags. The expulsion of great quantities of ascarides was accomplished; after which all the neuralgic symptoms entirely disappeared. I cannot conclude these desultory observations without offering my testimony in support of the superiority of the oil of turpentine over every other remedy in the treatment of worms. In the advanced and independent state in which these parasites exist in the intestinal canal, perhaps several agents have been found to occasion their expulsion; but in their pristine or embryotic condition, when enveloped in their mucous covering, I have met with no remedy capable of expelling, much less of exterminating them, except turpentine. The *worm-bags*, whilst entire, protect their inmates from the action of the ordinary Anthelmintics, and the extermination of intestinal worms cannot be accomplished unless these mucous citadels be overthrown. I am induced to hope, that these observations, although in themselves uninteresting, may have the effect of directing the attention of the readers of the *Medical Times* to this important subject; and that some of my professional brethren better qualified will illustrate the nature and treatment of intestinal worms.

Stokesley, June, 1849.

PROGRESS OF MEDICAL SCIENCE.

FRANCE.

(From our own Correspondent.)

The cholera continues to follow its decremental movement, and nothing, since my last letter, has occurred to confirm the apprehensions of the French press, viz., that a return of heat would be accompanied by a recrudescence of the epidemic. On the contrary, the disease has continued to vanish, almost in the arithmetical progression, of 20 per day; and we may safely conclude that before the close of the present month, its disappearance from the capital will be officially announced.' *En revanche*, it is spreading with great rapidity over all the Departments; but "sufficient for the day is the evil thereof:" let us confine ourselves, for the present, to Paris.

The following is the weekly return of mortality from cholera in the city and hospitals:—

	Deaths in City.	Hospitals.	Total.
21st	74	46	120
22nd	67	30	97
23rd	41	39	80
24th	32	32	64
25th	34	31	65
26th	37	40	77
27th	25	19	44
			547

The latest returns, though not yet officially made, indicate a still further decrement, and, as I said before, within a month, perhaps a fortnight, we shall have to announce the complete disappearance of this unwelcome visiter.

The gravity of the "sweating sickness," which prevails in many of the provinces, has, I am glad to say, been greatly exaggerated. From the accounts forwarded by the medical men, whom Government had dispatched into the provinces, it would seem that the disease yields readily to emetics of ipecacuanha and a cooling regimen. Amongst the deaths of the past week I have to record those of two members of our Profession. Drs. Ledure and Paulin-Debourg, attached to the *bureaux de secours*, fell victims to their zeal. The respected Chaplain of La Pitié, also, M. Delabare, who had never ceased during the epidemic from his labours, was attacked towards the end of last week and cut off in a few hours. The greatest efforts are being made to relieve the families of those thus unexpectedly removed. M. de Rothschild has subscribed 10,000 francs; the various public companies have given different sums, proportionate to their importance, and the National Guard has organised a system of domiciliary visits, which leaves open no door for refusal or excuse. But the poverty here is now so general that the collection will, I fear, be insignificant.

The journals relate, what they call some "curious" experiments on the contagion of cholera, recently made at St. Petersburg, by order of the Czar. They are not, as you will perceive, very conclusive; but, when so great a personage condescends to dabble in medical science, the least we can do is to notice his work. Four assassins, condemned to death, were compelled to sleep in the beds of patients who had died of cholera; the malefactors escaped the disease. They were then placed in the same beds with patients, who, they were told, laboured under cholera, (though really affected with other maladies;) the assassins were so terrified that they all died within three days. Such is the story; it seems rather apocryphal; but the Czar is a man *à part*.

The only matter worthy of notice which was discussed at the last meeting of the Academy of Medicine referred to a supposed case of "uterine polypus projecting through the walls of the abdomen." It occurred in the practice of M. Loir, and would be unique, if really such as it is described. M. Roux, however, thinks that the polypus must have been developed from the interstices of the walls of the uterus. M. Hugier, who examined the patient, appears to regard the case rather as one of hypertrophy of the uterine walls; and this is probably its true signification.

At the last meeting of the Academy of Sciences two subjects of popular interest—and, therefore, worthy of notice—were discussed. Although we have been accustomed to regard as fabulous the feats of fire-kings and other like charlatans, it is certain that, under circumstances which have not yet been clearly ascertained, the human body, or, rather, parts thereof, is capable of supporting, uninjured, an extraordinary degree of heat.

If I remember right, it was M. Boutigny who first demonstrated the fact that it was possible, without the slightest injury, to dip a finger into a

mass of melted lead and cut with the hand a jet of liquid metal. The experiment, probably, did not find much favour amongst scientific amateurs; but it has been long familiar to the workmen employed in blast furnaces, and has recently been confirmed by M. Perry, from whose communication I select the following extract:—

"On the 3rd of June (writes M. Perry) I visited the blast furnace at Val-Suzon, near Dijon. I asked the workmen whether any one of their comrades ever ventured to place a foot on the molten metal, and they immediately indicated one who was in the constant habit of making the experiment. The man commenced by sweeping clean the metallic fluid, which had been melted about a quarter of an hour previously. He then carefully removed every particle of sand or dust from the soles of his feet, and then placed them successively on the surface, leaping from one foot to the other. Encouraged by the result, I stamped three times on the incandescent metal, but I confess that I had not the courage to walk upon it. At the expiration of a quarter of an hour, we could distinguish the marks of our feet, and in half an hour the footsteps were perfectly delineated in a dark brown trace, which offered a striking contrast to the brilliant redness of the metal."

The other subject noticed by the Academy of Sciences referred to a new alimentary plant brought from South America by M. Picquot. The learned traveller, indeed, had brought home with him *two*; but it turned out that one of them, the *Apios tuberosa*, had been cultivated in France for the last hundred years. The other, *Psoralea esculenta*, is entirely new, and seems destined to take a high rank amongst our nutritious vegetables. It grows well in elevated, and apparently barren situations, and is easily preserved by drying. The French agriculturists appear to have much confidence in the result of the experiments about to be made with this interesting vegetable, which promises to rank next to the potato.

You are, doubtless, familiar with the recent experiments, which appeared to demonstrate an intimate correlation between muscular contractions and the development of electricity. These experiments have been repeated by M. Matteucci, the highest authority in matters of this kind; and he writes to the Academy to state, that he has not been able to establish the relation of cause and effect between the two phenomena. The needle, it is true, undergoes a deviation after each muscular contraction; but the deviation is not in proportion to the energy of the muscular effort, nor is the direction of the needle constant.

One of the many advantages which Paris enjoys over London is, as everybody knows, the number and cheapness of its bathing establishments. In all the populous quarters a warm bath can now be obtained for ten sous,—something less than fivepence,—and it is probable that even this moderate price will soon be diminished, thanks to M. St. Leger, head engineer of the mineral district of Rouen. M. St. Leger proposes to employ a portion of the warm water which escapes in waste from the numerous manufactories of the town, for the purpose of establishing public washing-houses and baths, open to the indigent *gratis*, and to the poorer classes at a very low price. His calculations demonstrate that the first cost of an establishment, in the neighbourhood of one of the manufactories alluded to, would not exceed 60*l*., nor the annual expense 80*l*.; which latter would be amply covered by the receipts. The Corporation of Paris is about to take the matter up, and it may be well worthy the attention of those to whom the care of the "public health" is entrusted in our large manufacturing towns, where the "great unwashed" are so numerous and so neglected.

An interesting experiment, the results of which may be important, was lately made at the laboratory of the School of Chemistry. An immense quantity of carburetted hydrogen was obtained from wine lees by the simple application of heat. The gas was well suited for the purposes of lighting, and it is expected that the refuse of the wine-tubs may be turned to a good account. Perhaps, the refuse of our breweries might answer as well.

The authorities paid a visit to M. Baral, Professor of Chemistry, at the Polytechnic School, on Saturday last, for the purpose of seizing him; but, while the police officers were seeking proofs of "treason" in the crucibles, the worthy Professor slipped out through a secret door, and has not been heard of since.

TREATMENT OF CHOLERA.

Dr. Handvogel has published, in the *Union Médicale*, a method of checking vomiting in cholera, and thus preventing the ejection of medicines. He obviates this great inconvenience by means of the hydro chlorate of morphine, which he uses endermically; that is to say, he makes a slight incision in the epigastric region and applies the drug He assumes that he thus succeeds in checking both the vomiting and purging.

Dr. Lecœur, Professor of Materia Medica at Caen, recommends the chlorate of gold, and strychnine in cholera, which he conceives to be a purely nervous disease, depending upon a certain electro-magnetic state of the atmosphere, in consequence of which there is an undue subtraction of electric fluid from the body. Hence the Professor proposes, by strychnine and the chlorate of gold, to stimulate the ganglionic system, the seat, according to him, of the disease.

Dr. Manget, of Paris, uses the sesqui-chlorate of carbon. He recommends general friction to be persevered in, and assures us the exhibition of the carbon is followed by a profuse perspiration. At the end of three hours he generally finds it necessary to administer a second dose, but seldom a third. He says this preparation of carbon is the most powerful diaphoretic with which he is acquainted.

Dr. Taulier, of Saint-Victor-Lacoste, uses the sulphate of quinine in the treatment of cholera, and, as he says, with the happiest results.

Dr. Bonet, a physician of Paris, informs his Professional brethren, that, in a great number of patients affected with cholera in the last stage, that to say, when the pulsation of the heart and the movement of the pulses are absent, and in the commencement of the blue stage, he has succeeded in restoring the action of the heart, and in recovering the patient from the blue stage by administering, at intervals of half an hour, four cups of a hot an sweetened infusion of the common lime-tree, mint, balm, or chamomile, &c., in each of which cup of infusion were four drops of volatile alkali, making sixteen drops, which the patient may take in two hours. The reaction (he says) is almost instantaneous—the pulse commencing almost instantaneously to beat, rather irregularly at first, but afterwards with force, the blue state disappearing, the body face, and extremities being covered with hot and copious sweat, and in a few hours the patient is entirely out of danger.

A Mr. Royer, surgeon to the Garde Mobile claims the merit of having *discovered* an infallible remedy in "brandy and salt." The worthy Mobile seems to be ignorant of the writings of Solomon.

For ourselves we wonder, with all these remedies, that patients will continue to die of cholera. We have little faith in any one of them.

DRY CUPPING IN INTERMITTENTS.

Dr. L. F. Goudret has, in a little Pamphlet lately published, urged the advantages to be gained in the treatment of intermittent fever, by the application of dry cupping glasses in the vicinity of the spinal cord. He directs from eight to ten glasses to be applied on either side of the vertebral column the moment the cold stage sets in, and he affirms that, if this be done, the paroxysm will be cut short. Dr. L. F. Goudret does not appear to have been very successful in persuading his medical brethren of the truth of his assertion, or he would hardly have been reduced to the necessity of heading his *brochure*, "Traitement de la Fièvre Intermittente mis a la portée du Public."

Dr. Goudret's plan of treating intermittents appeared at full length, in his own words, in a letter in the *Medical Times*, from the Doctor himself, Jan. 20, 1849.

GERMANY.

[From our Berlin Correspondent.]

If a Berlin medical man meets an acquaintance, the second question which he puts to him—for the first is always on politics—is, "Will the cholera spread itself in Berlin?"

It has made its re-appearance amongst us during these last three weeks, but has as yet satisfied itself with about forty victims, to which number each quarter of the town has furnished its proportion. Will the sword of Damocles fall on our heads, or shall we be let off for the mere fear? Last year we had a man who could resolve our doubts. An empiric did, like a Roman Haruspex, from the tenor of circumstances, foretel that the cholera would not, as the world at large expected, make its appearance at Berlin in the spring, but in the autumn. Nevertheless, the charlatans have not as yet expressed their opinion on the epidemic of this. The town of Breslau has, for the second time, been most terribly visited by this scourge. The terror was still more increased by the frequency of sudden deaths. Whoever could leave the town took refuge among the mountains of Silesia, in order to inhale their pure air. At present the cholera is on the decrease there. At Halle, a town with a population of 30,000 souls, the relative number of deaths was still greater. More than the thirtieth part of the population succumbed to this malady.

Permit me, in the absence of novel medical matter, to give you some remarks on the medical statistics of Prussia. They are grounded on copies of several Tables published at our "Statistic Office." In the end of 1846 (the census takes place triennially) there were in Prussia, on an area of 5080 square miles, (German measure,) and with a population of 16,110,000, 5137 private physicians, 351 army doctors, 827 surgeons of the first class, 1144 surgeons of the second class, 1423 druggists, and 11,539 midwives. Thus, if the distribution of the population and of medical aid in all the provinces Prussia were equal, you would have one physician to every square mile with 3000 inhabitants; to every 11,000 inhabitants one druggist; and to every 54 births one midwife.

These data, unfortunately, are only chimerical; for it is proved, from official Reports, that we possess a great number of districts with a population of from 10 to 12 and even 16,000 inhabitants, and located on 8 or 10 square miles (German) on which there is only one medical man; and on a surface of 10 to 15 square miles (German) with a population of from 30,000 to 40,000 only one druggist. These neglected localities are situate principally in the provinces of East and West Prussia, in Pomerania and Upper Silesia. The provinces of Middle Prussia are the best provided with medical aid. In the town of Berlin (possessing a population of 410,000 inhabitants) there 318 private physicians, 41 army doctors, 20 surgeons of the first, and 51 of the second class, 34 druggists, and 59 midwives.

The proportion of mortality in Prussia is 1 in 34, and in this respect it stands nearly on a footing with Austria and Russia, where the mortality is 1 in 33. On the contrary, in France and England, the proportion of deaths keeps up with the increase of population, as 1·40 and 1·44. The difference of mortality in the several parts of Prussia is very great, so that, while in one part of the Kingdom, (for example, Berlin, Westphalia,) 1 death occurs among 41 persons; in other parts (West Prussia), almost every 27th individual dies.

The proportion of births to the number of living is on an average as 1 in 25.

Before the completion of the first year of existence in the western provinces, 1 out of 5 or 6 infants dies, and in the eastern provinces 1 out of 4 or 5.

The number of persons who die from old age greater in the western and central provinces than in the eastern; for, while in the neighbourhood of Trêves and Aix-la-Chapelle 14 to 15 per cent. of all kinds of deaths proceed from this cause, 8 to 10 per cent is the highest average in the neighbourhood of Dantzic and Konigsberg. In Berlin only 6½ per cent. of deaths belong to this category. The number of births out of wedlock

is greatest in Berlin, where every sixth child is illegitimate. Next to this city, the provinces of Silesia and Saxony can boast of the greatest number, viz., 1 in 11; while in the Rhenish provinces only 1 child out of 32 is illegitimate.

Generally speaking, we may draw the following conclusions from the data contained in the above official tables:—

1st. That where the greatest opulence exists, the number of birth is the smallest. That opulence, which encourages intellectual and social refinement, which creates innumerable worldly enjoyments, causes the mutual relation of the sexes to lose that *exclusively material character* which it possesses amongst uncultivated people. The neglected population of the Upper Silesian villages, with whom, for instance, drunkenness and coition were the chief sources of enjoyment a few years back, increased remarkably until the occurrence of typhus in 1847. Affluence at the same time diminished, for the proportion of dwelling-houses (huts with one room) was to the proportion of increase of population as 20 to 1. At present, indeed, the population increases but slowly, and the cause of this is to be found in the prostration of the vital strength which characterises the people since the introduction of Temperance Societies and the invasion of the typhus.

2ndly. The mortality is not always in direct proportion to the number of births, but is always greater and less according to the degree of refinement and opulence of the people.

3rdly. Has the number of medical men any perceptible influence on mortality? There are sceptics who maintain, that it is not more possible for medical men to limit the mortality amongst mankind, than it is for clergymen to decrease immorality. Our tables come to the following conclusions, that the maladies inherent to human nature can be classified into *acute*, *chronic*, and *uncertain*, (*i.e.*, such as are not treated by medical men). Thence, in those localities where a small number of medical men practise in an extensive field, the deaths are in consequence *acuter* and more *uncertain*, and illness much more frequent than elsewhere. From this we may infer, that, at least, in this respect, the activity of medical men has influence on the mortality. Nevertheless, in arriving at a fair and natural view of the causes of mortality, we think, that in many places where medical advice is scarce, the deficiency of the medical staff has much to do with it.

AMERICA.

INFLUENCE OF POSITION IN THE CURE OF TRISMUS NASCENTIUM.

Dr. J. W. Clement relates, in the *American Journal of Medical Sciences*, the cure of an infant to whom he was called two weeks after its birth, in consequence of a supposed attack of croup. He found the child lying on its back in spasms, with a hard croupy respiration, the head somewhat elevated by a large pillow for the purpose of relieving the respiration. The head, on examination, presented an unusual form. The occipital bone was much depressed, the posterior edges of the parietal bones riding over it, forming a strong and well-defined ridge. The disease was at once suspected to be that of trismus nascentium. The child was placed on its side, in order to remove the pressure from the posterior part of the head, and in half an hour the spasms ceased, and the breathing gradually became more free. By attention to the position of the child in the cradle no unfavourable symptoms returned.

MEANS TO REMEDY THE BRITTLENESS OF NITRATE OF SILVER CRAYONS.

M. Chassaignac proposes that, in the centre of the stick of caustic, a fine platinum wire should be placed. M. Blatin recommends that a wick of cotton be placed in the mould previous to the introduction of the fluid nitrate of silver.

IRON ROD, WEIGHING 13¼ POUNDS, DRIVEN THROUGH THE HEAD—RECOVERY.

Dr. J. M. Harlow records, in the *Boston Medical and Surgical Journal* (Dec. 13th), the following remarkable case:—A man, twenty-five years of age, of vigorous constitution and temperate habits, was charging a hole preparatory to blasting, when the powder exploded, driving the tamping iron against the left side of his face, immediately anterior to the angle of the inferior maxillary bone. Taking a direction upward and backward towards the median line, it penetrated the integuments, the masseter and temporal muscles, passed under the zygomatic arch, and (probably) fracturing the temporal portion of the sphenoid bone, and the floor of the orbit of the left eye, entered the cranium, passing through the anterior left lobe of the cerebrum, and made its exit in the median line, at the junction of the coronal and sagittal sutures, lacerating the longitudinal sinus, fracturing the parietal and frontal bones extensively, breaking up considerable portions of brain, and protruding the globe of the left eye from its socket, by nearly one-half its diameter. The tamping iron is round, and rendered comparatively smooth by use. It is pointed at the end which entered first, and is 3 feet 7 inches in length, 1¼ inch in diameter, and weighs 13¼ pounds. The patient was thrown upon his back, and gave a few convulsive motions of the extremities, but spoke in a few minutes. He was carried to an ox-cart, in which he rode, sitting erect, full three-fourths of a mile to a house. On his arrival there, he got out of the cart himself, and, with a little assistance, walked up a long flight of stairs, where he was dressed. When seen by Dr. Harlow, an hour and a half after the accident, he was perfectly conscious, but was becoming exhausted from the hæmorrhage, which was very profuse, both externally and internally, the blood finding its way into the stomach, which rejected it as often as every fifteen or twenty minutes. Pulse sixty and regular. His person, and the bed on which he laid, were literally one gore of blood. Assisted by Dr. Williams, of Proctorsville, who was first called to the patient, Dr. Harlow proceeded to dress the wounds. From their appearance, the fragments of bone being uplifted and the brain protruding, it was evident that the fracture was occasioned by some force acting from below upwards. The scalp was shaven, the coagula removed, together with three small triangular pieces of the cranium, and in searching to ascertain if there were other foreign bodies there, Dr. Harlow passed in the index finger its whole length, without the least resistance, in the direction of the wound in the cheek, which received the other finger in like manner. A portion of the anterior superior angle of each parietal bone, and a semicircular piece of the frontal bone, were fractured, leaving a circular opening of about 3½ inches in diameter. This examination, and the appearance of the iron which was found some rods distant, smeared with brain, together with the testimony of the workmen, and of the patient himself, who was still sufficiently conscious to say that "the iron struck his head and passed through," was considered, at the time, sufficiently conclusive to show not only the nature of the accident, but the manner in which it occurred.

The spiculæ of bone having been taken away, a portion of the brain, which hung by a pedicle, was removed, the larger pieces of bone replaced, the lacerated scalp was brought together as nearly as possible, and retained by adhesive straps, excepting at the posterior angle, and over this a simple dressing—compress nightcap, and roller. The wound in the face was left patulous, covered only by a simple dressing. The hands and forearms were both deeply burned nearly to the elbows, which were dressed, and the patient was left with the head elevated, and the attendants requested to keep him in that position.

Antiphlogistic remedies were vigorously employed from the 13th of September, the day on which the injuries were received, to the 3rd of October, during which time the patient lay in *a semi comatose state, seldom speaking unless spoken to, and then answering only in monosyllables.* During this period, fungous growths started from the brain, and increased rapidly from the orbit. To these was applied nitrate of silver cryst., and cold to the head generally. The dressings were renewed three times in every 24 hours; and in addition to this, laxatives, combined with an occasional dose of calomel, constituted the treatment. The pulse varied from 70 to 96—generally very soft. During this time an abscess formed under the frontalis muscle, which was opened on the 27th, and has been very difficult to heal. Discharged nearly ℥viij at the time it was punctured. On the 5th of October he began to improve, and by the middle of November every unfavourable symptom was removed, and the patient appeared quite well.

DEATH FROM PRESSURE OF AN ENLARGED THYROID GLAND.

Dr. F. H. Hamilton presented to the Medical Society of the State of New York (Feb., 1849) a cast in plaster of an enlarged thyroid gland, with the trachea attached, which had been removed from a patient after death. Dr. Hamilton stated the history of the case to be as follows:—During more than twenty years the patient had suffered from occasional paroxysms of difficult breathing, which he at first supposed to be asthma. The difficult respiration had, however, gradually increased, accompanied with a steady enlargement of the thyroid gland, especially on the right side. During several months preceding his death his sufferings were extreme and unremitting, and the most skilful treatment failed to afford the least permanent relief. A few weeks, however, before the fatal event, he had experienced temporary relief from a sudden discharge of a small quantity of grumous matter through the trachea.

Dr. Hamilton saw him in the early part of January, 1849. At this time he had not slept for several days, except when for a minute or two he voluntarily suspended the act of respiration. The trachea was pressed forcibly to the left, being displaced in this direction about one inch. Upon consultation it was determined that in this condition he could survive but a few hours, and that an operation was demanded. Dr. Hamilton, knowing well the formidable character and connexions of the tumor he had to deal with, did not at any time propose to remove the gland, but suggested the possibility of prolonging life by removing the pressure of the muscles and fascia which bound it against the trachea. Accordingly, he cut across the neck, from the posterior edge of the sterno cleido-mastoid to the centre of the trachea, traversing all the textures down to the tumor. But neither this nor the elevation of the tumor with the tenaculum diminished the difficulty of breathing. He then dissected up, and cut off that portion which lay in front of the trachea. But the breathing continued the same. With two ligatures and applications of snow, the hæmorrhage from the incision upon the gland was soon arrested. It now became apparent that the trachea was permanently narrowed by the long and continued pressure, and the operation of tracheotomy was made below the tumor as a final and only resort. Through this opening he continued to breathe quietly and freely until his death, which occurred three days after.

The *autopsy* disclosed the following facts:—The right thyroid lobe enlarged to about five inches in its transverse diameter, and degenerated; containing several imperfectly formed cysts filled with grumous matter. One of these cysts, with a portion of the hypertrophied structure, was situated directly behind the trachea, occupying all the space between the cricoid cartilage and the sixth or seventh cartilaginous ring, and encroaching upon the tube from this direction so as to effect an almost complete closure; leaving only an opening of about two lines in diameter. The left lobe was also considerably hypertrophied, and degenerated in the same manner with the right.

SUPERFŒTATION AND MIXED BIRTHS.

Dr. Thomas B. Taylor, of Princeton, Miss., relates (*N. O. Journ.*) the following as a case of superfœtation:—A negress, aged about thirty-five years, in May last, was delivered of twins; one a mulatto, and the other a negro child. She had been married to a negro man on the plantation, of delicate constitution, for many years, and had had several children by him. Her menstrual discharge

had occurred for several months previous to her pregnancy, at about the full of the moon. She felt herself pregnant by her customary signs, about the middle of the month; and, to confirm her suspicions, at the next period it did not appear. About three weeks from the time she had first felt she had conceived, and one week after her menses had failed to appear, she had sexual intercourse *once* with a white man. She slept with her husband every night, —had connexion with him the night before she had intercourse with the white man, but not on the same night. At their birth the mulatto child bore marks of being at least three weeks younger than the negro; thus sustaining the woman in her suppositions as to the time between her two conceptions

CASES IN WHICH A LARGE QUANTITY OF CHLOROFORM WAS USED.

Professor Jackson related a case in which a remarkable quantity of chloroform was used. A lady labouring under a stricture of the upper portion of the rectum, which prevented the flatus from passing became, in consequence, the subject of an enormous distension of the abdomen, attended with so great degree of sensitiveness, that the use of palpitation and percussion were entirely precluded, and her case was at first involved in no little obscurity.

In the latter part of the month of December, 1845, she was attacked by a violent convulsive paroxysm, preceded by a very peculiar spasmodic affection, consisting in a cracking of the head of the humerus in the glenoid cavity, and of the femur in the acetabulum; these spasmodic symptoms continued for about fifteen minutes, when general convulsions set in, accompanied with intense pain. On the 1st of January, 1846, an attack of spasms occurred and continued for several hours; the urine was retained from a spasmodic affection of the neck of the bladder and urethra, the orifice of which latter was so much retracted, that it was difficult to introduce a catheter to relieve the distension of the bladder. A few drops of chloroform were given to the patient to inhale, and prompt relief was experienced. The use of the chloroform was continued daily for two or three weeks, the quantity being gradually increased as the effects diminished. Dr. Jackson was sent for one morning and found the mother of the lady in great alarm in consequence of the quantity of chloroform which her daughter had taken. She had inhaled two ounces in the course of the evening, then two ounces more, and an additional ounce in the course of the night; being five ounces inhaled from 5 o'clock p.m. until 10 o'clock of the ensuing morning. Dr. Jackson found her with a feeble pulse, diminished temperature of the body, and considerable excitement of mind. She insisted upon having more of the ether to inhale. She remained cold and nearly pulseless for forty-eight hours, when all effects of the inhalation disappeared, and, what is remarkable, since that time she has had no return of her spasms. Upon one occasion having a tooth taken out, the pain of the operation caused a tendency to their return, but this went off without the spasms occurring.—*Trans. Phila. College of Phys.*, Vol. II. No. 6.

LOCAL ANÆSTHESIA IN NEURALGIA.

Dr. Hays stated, that he had employed the chloroform to produce local anæsthesia with apparently the most happy effects, in a case of neuralgia, occurring in a gentleman fifty years of age, who had been for a long time a sufferer from neuralgia of the foot, in which all the remedies that had been previously employed failed to produce relief. When Dr. Hays was called to this patient, he found him in intense pain, which had deprived him of sleep the whole of the preceding night. Dr. Hays directed the affected parts to be enveloped with a pledget of lint or a few folds of muslin wet with chloroform, and the whole to be covered with a portion of oiled silk to prevent evaporation; on the next morning he found him entirely free from pain, which has not since returned. Whether the relief experienced in this case is to be ascribed to the local anæsthesia produced by the chloroform, or is to be considered as a mere coincidence, Dr. Hays does not pretend to decide.—*Ibid.*

Since this communication was made to the College, the further history of the case has shown, that an arrest of the paroxysm is always accomplished by the application of the chloroform; and to the use of the article, several other similar cases have been attended with like results.

ETHER IN NEPHRITIC COLIC.

Dr. Stillé stated, that, last spring, Dr. Bowditch, of Boston, related to him a case of nephritic colic, occurring in an individual who had previously suffered from several attacks, in which the chloroform had been administered with the effect of inducing entire relief of the pain, without abolishing consciousness. The influence of the chloroform was kept up for several hours, when, at length, the stone passed through the ureter. Within the last three weeks, a lady, about 20 years of age, after retiring to bed some hours, was attacked with violent pain in the region of the right kidney. About an hour afterwards (one o'clock, a.m.) Dr. Stillé was sent for. The mother had applied warm fomentations to the loins, and immersed the feet in a mustard bath. There was still intense pain, with tenderness over the region of the right kidney. The patient was lying bent double, her hands and feet were cold, her pulse feeble, and about sixty in the minute. The pain extended in the direction of the ureter; there was pain and a twitching motion of the right thigh, with frequent inclinations to urinate. From a review of the symptoms, Dr. Stillé considered the case to be one of nephritic colic. The use of ether was suggested. A teaspoonful was poured upon a handkerchief, and inhaled for five minutes, when the patient fell asleep. In about fifteen minutes she was aroused by a return of the pain. The ether was again inhaled, and its impression was kept up for about an hour, without carrying it so far as to abolish consciousness; the pain ceased, the extremities became warm, and the pulse rose to seventy-five. The next morning there was no pain complained of, but considerable soreness was experienced when pressure was made over the right kidney. The pain did not return until two nights afterwards, when a larger dose of the ether was used by the patient without Dr. Stillé's presence or direction, but from some cause it did not produce the same alleviation of the pain as before. At four o'clock in the morning Dr. Stillé saw her. The pain had by this time somewhat abated, and upon the administration of an opiate enema complete relief was procured. The pain has not since returned. No calculus was passed, so far, at least, as could be ascertained.—*Ibid.*

ON THE DEVELOPMENT OF THE PURKINJEAN CORPUSCLE IN BONE.

Dr. Joseph Leidy says, in the proceedings of the Academy of Natural Sciences of Philadelphia, the mode of development of the Purkinjean corpuscle, as noticed upon the upper or posterior border of the os frontis, is briefly as follows:—After the primitive ossific rete has been formed from the deposit of the osseous salts, enclosing groups of cartilage cells in the areola, the further deposit takes place in a fibrous or line-like course from the parietes of the areola of the primitive osseous rete, in the interspaces of the cartilage cells nearest to, or in contact with the sides of the areola. At this period the cells shoot out or extend their canaliculi between the fibrillæ just formed, and then the cell-wall and continuous walls of the canaliculi fuse with the translucent, homogeneous, or hyaline substance of the cartilage existing between the cells and the osseous fibrillæ, and with the fibrillæ themselves, by the deposit of the osseous salts. The period of the formation of the canaliculi appears to be quite definite, occurring during the deposit of the osseous salts, and not before. To such an extent is this the case, that I noticed in several instances cells which had formed their canaliculi upon the side which was ossified, while upon the other side I could not distinguish any trace of them.

During the whole time of the formation of the Purkinjean corpuscle, the nucleus remains unchanged; at least no change is perceptible in it beneath the microscope, and by applying tincture of iodine to the preparation, which turns the nucleus brown, I was able to detect it within the perfected Purkinjean corpuscle, not only corresponding to the nucleus of the remaining unossified cartilage cells in granular structure, but also in its measurements. After the Purkinjean corpuscle has been formed a short time, the nucleus dissolves away or disappears.

The newly-formed Purkinjean corpuscle is about the same size as the remaining unossified cartilage cells, as indicated in the list of measurements appended to these notes.

Size of cell of temporary cartilage, from the unossified os frontis of a human embryo, 1-1886th of an inch; nucleus of ditto, 1-3125th of an inch; nucleolus, 1-8333th of an inch; Punkinjean corpuscle, 1-1865th of an inch; nucleus within the same 1-3030th of an inch.

PROGRESS OF PHYSICAL SCIENCE.

ETHNOLOGICAL SOCIETY.—May 23.

Sir Charles Malcolm, Vice-President, in the Chair.

ON THE NATIVES OF ULLADULLA, NEW SOUTH WALES.

By J. P. Townsend, Esq.

Well do I recollect when first I met these primitive fresh-water sailors, paddling along in a little fleet. Their presence added not a little to the interest of a novel landscape; and I was astonished by their vociferation and by their hail in a strange jargon. As usual, they were surrounded by an atmosphere of hilarity; and their merry peals of laughter ran loudly. The men are darker than the younger women. Indeed, their colour is much that of soot. The half-casts are of a light yellow complexion. A few of the men wear opossum cloaks. They have short beards, which being grey in the older men, has a very singular appearance when contrasted with their black faces and glimmering eyes. Their weight must be comparatively very trifling, their limbs being of the smallest possible size. It is rarely that a man is found among them who is not perfect in stature, in limb, and in activity. They are excellent mimics, and seize, in a moment, on any peculiarity that marks the white man; even on the pronunciation of a Devonshire boy, or the gruff manner of a captain in the navy. They can at any time supply themselves with 'possums, bandicoots, kangaroos, fish, wild-fowl, honey, and gum, for the country around Ulladulla is wild and but partially settled. Like the Australians, generally, they have a notion of a Being whom they by no means worship, but, on the contrary, attempt to outwit, called the Devil Devil; and he, they think, will do them a mischief if he have an opportunity; for instance, carry them off in the dark. They sometimes carry a body about with them for months, sewed between two sheets of bark, in order that, by reason of their prolonged wanderings, the spirit of the deceased might not be able to track them, and bring the Devil Devil in its train. They ultimately bury the body in a deep grave, the gins (wives) waiting around and repeating, with rapid utterance, a doleful chaunt, whilst the tears stream down their cheeks. They number about 400. They used, occasionally, to hold great meetings for the purpose of playing at foot-ball, and certainly finer figures than the naked players exhibited could not be desired. On such occasions they wear only the maro, a belt round the abdomen, and depending from it, both before and behind, tails formed of the fur of the kangaroo. The same fate awaits this interesting people that has befallen the Botany Bay tribe, of which only one individual remains. He is very intelligent, and has a ten acre piece of ground, and some "white fellow" tenants.

THE YAKHAS (DEVIL WORSHIPPERS), NOW CALLED VEDDAHS, THE ABORIGINES OF CEYLON.

By Charles Pridham, Esq.

June 20.—Throughout the wild range of the British empire (remarks Mr. Pridham), there is, perhaps no remnant of a once numerous people which has a stronger claim the consideration of the ethnologist than the Veddahs of Ceylon. Forming,

in ages too remote for the historian to fathom, one of the aboriginal races of the island, they appear, from a combination of circumstances, to have preserved in a great degree the peculiarities of race, language, and manners known in later days by the name of Bedas, Weddahs, Vaddahs or Veddahs. This race inhabits a vast tract of forest country, with an area of nearly 2,000 square miles, denominated Veddah Ratte and Maha Veddah Ratte, the former adjoining the district of Bintenne, and the latter the district of Welasse and Ouva, the whole being bounded to the east by the district of Batecalo; to the south by the Mahagama, Pattoo, and Ouva to the west and south-west by the Kandian mountains, and to the north by the Mahanette Ganga. These people are divided into two communities, varying considerably in their manners and mode of life. One, called the wild or forest Veddahs, build their huts in trees, live in pairs, only occasionally assembling in greater numbers, and exhibit no traces of the remotest civilisation, nor any knowledge of social rites; the other called the village Veddahs, who may be said to be a link between the Singhalese and their wilder brethren, congregate in villages, live in tents, and cultivate,—if scratching the earth, scattering seed, and striking roots into the ground, can be dignified with such an appellation,—small patches of Kurykkan maize, and a wild species of bringal. In times of scarcity they will eat decayed wood, mixed with honey, and made into cakes, but this is not so much for nourishment as to distend their empty stomachs and allay the distressing feelings of hunger. Until recently, the Veddahs had Kandians of the neighbouring districts for headmen, through whom they kept up a sort of communication with the Government; but this was, to some extent, a source of their degradation, for their wild nature was exaggerated, and no pains were taken to amend their habits, extend their comforts, or improve their appearance. The appearance of this people is remarkable for the intensely wild expression of the features, by no means diminished by their bushy, matted, and discoloured hair, which from being never cut or cleaned, hangs down, and shades the face in a very disgusting manner. They are of moderate stature, seldom exceeding five feet five inches in height, but are well made, and full of activity. Their dress is the scantiest covering that can possibly be used, consisting of a small piece of cloth depending in front from a string tied round the loins, to which a small bag is frequently attached. They never till the soil, their food being confined to flesh and fish. Deer's-flesh they cut into long slices, and, after dressing it in the sun, cut a hollow in a tree, and putting a sufficient quantity of honey at one extremity, fill up the centre with flesh, and cover the exterior with clay. This is their reserve for times of scarcity. They have hardly any knowledge of numbers, and cannot count above five, and are wholly ignorant of the virtues of medicinal plants. They observe neither the rites of marriage nor burial, their dead being consigned to the wild beasts of the jungle. Without any regular religion, the Veddahs, like every other wild race, appear sensible of the existence of an invisible and superior Power, which exhibits its influence by undefined terrors,—hence their belief in and worship of evil spirits. They also make offerings to the shades of departed ancestors, and to figures temporarily prepared to represent the controlling spirit of some planet which they believe to exercise an influence over their fate. It is probable that the country now occupied by this people is daily becoming narrowed by the extension of pastoral operations on the part of the Moorish and Tamul population in the eastern province, no less than by the cocoa-nut planter on the coast. Thenceforth there is a special mission for the friends of humanity.

ROYAL GEOGRAPHICAL SOCIETY, JUNE 25.

Captain SMYTH, R.N., President, in the Chair.

Sir Wm. Kay, Bart., and Edward Gordon, Esq., M.A., were elected Fellows of the Society.

Papers read.—1. "A proposal for the Construction of Maps upon the walls of the Corridors and Committee-rooms of the New Houses of Parliament," by Mr. Saxe Bannister, with remarks upon the subject by Mr. G. Bellas Greenough V.P.R.G.S. 2. "On Abila and the district of Abilene, near Mount Lebanon," by Mr. J. Hogg, F.R.S., Hon. Sec. 3. "Notes on the Physical Geography of Palestine," by Col. Von Wildenbruch. 1. Mr. Bannister proposes the construction of maps on a large scale as useful decorations to the New Palace at Westminster, and similar to those in *the Gallery of Geography of the Vatican*. One series of maps would present to the eye pictures of the whole globe—the forests of the Canadas in contrast to the houses and the harvests so rapidly thinning them—the fisheries of Iceland, Greenland—the fur regions of Hudson's Bay, and the tales of lost, as well as the tract of successful, explorers of the frozen North—the West India Isles—the free, peaceful, and Christian settlements of Western Africa, in contrast with its manshuts and its slave-marts—the sheep-walk and the mission-house, so rapidly driving back barbarism far into South Africa—the mines and stock-stations already pushed deep into the Australias—the varied works of nature and of man in New Zealand, in Ceylon, in India, in the Asiatic Archipelago, in the islands of the Southern Ocean, and in China. To these scenes of British enterprize would be added correct delineations of the rest of the globe, with each tribe and people distinctly characterized, and with the traces of great events, now visible in monuments or in ruins, correctly displayed to the eye. These maps drawn according to the best resources of modern science, should be on the largest possible scale, and uniform in magnitude. In addition to such maps of the land, there should be carefully prepared a collection of marine maps—not mere charts, but more complete even than those already suggested by Humboldt, for the shallows, the depths, the currents and trades of the ocean. Another series would form a history of Geographical discovery. A third would include the representation of the elements of intelligence found in the rude Geographical designs of the Esquimaux, the Indian, and the native of Australia, to guide the colonist to rich pastures, to relieve the explorer in his perplexity, and sometimes to warn the civilized man that even the savage understands his territorial rights.

Mr. Greenough would prefer, to the series of maps suggested by Mr. Bannister, a series of cartographic compositions. The physical map of Berghaus might be taken as a rude type of this desideratum, be more diversified in character and subject, enlarged in scale, and wrought up to a degree of excellence which an alliance of art, science, and literature can alone produce. It would be desirable, also, to have two Georamas,—the one for inanimate nature, the other for man in his several relations, and for the changes which the surface of the globe has undergone under his operations. An empire over which the sun never sets requires of its rulers, and in a minor degree of its people, a familiar acquaintance with the entire globe. The affairs of our forty-three colonies are administered at home by a staff so small, that, on an average, two clerks are all that can be spared for each; and surely the labours of these officials should be eased, by placing at their disposal the readiest means of acquiring standard information; nor does it appear less expedient that Members of Parliament should have distinct ideas upon those respective colonies whose interests and capabilities are often mainly dependent on geographical position and local considerations, and in respect to which they may be at any time called, upon a short notice, to assent to or dissent from complicated legislative enactments.

We much regret that space will not allow us to give our readers more than a brief analysis of this very important communication.

DR. GREGORY, Physician to the London Small Pox and Vaccination Hospital, has removed his residence from 31, Weymouth-street, Portland-place, to 6, Camden-square, Camden New Town.

TO SUBSCRIBERS.

The remainder of the Index, and the Title to Vol. XIX., will be given in our next Number. Subscribers in want of any of the back Numbers are recommended to complete their sets.

Cases for binding the volumes, price 2s. each, are now ready for delivery. Portfolios, for preserving the weekly Numbers, price 3s.

New Subscribers will oblige by forwarding their Names direct to the Office, 147, Strand, or to the News Agents or Booksellers. All Post-office Orders should be made payable to the Publishrse WM. S. ORR AND CO.

THE MEDICAL TIMES.

SATURDAY, JULY 7, 1849.

In the First Number of a New Volume, it will not, perhaps, be thought out of place by the majority of our readers that we should take a brief retrospect of our editorial labours, adverting also to the provision we have made to secure and maintain our position amongst the medical periodicals of the British Empire.

In a Journal so extensively circulated as the *Medical Times*, it was necessary, so far as possible, to suppy the wants and meet the wishes of a large number of the different orders which compose the Profession. Our strenuous endeavours have been to effect this; and we appeal with confidence to our last Volume, to prove that no department of medical science has been neglected, while we have unceasingly advocated those great principles which are necessary to the general welfare and increased usefulness of our brethren.

The Lectures which we have published—if we regard the Professors by whom they were delivered—the depth of scientific research which they display—their variety and adaptation to the present wants of the Profession—are unparalleled in the history of hebdomadal medical Journalism—embracing as they do, the excellent discourses of Mr. Macilwain, on "Fever," which have excited the greatest attention of the Profession both in this country and the United States. The Gulstonian Lectures, delivered at the Royal College of Physicians, by Dr. Gull, whose talents received a well-merited compliment, when he was selected by the members of the most ancient, and one of the most learned medical Corporations of this kingdom. In Psychology, the Croonian Lectures, delivered at the same College by Dr. Conolly, one of the first authorities in Europe in this department of science. In Materia Medica, the interesting and instructive Lectures delivered before the same learned Corporation by the celebrated Dr. Golding Bird. In Surgery, Lectures by the veteran Mr. Guthrie, whose experience in military surgery is not surpassed. On Physiology, the Lectures of the first comparative anatomist in Europe, the learned Professor Owen, on the "Generation and Development of the Invertebrated Animals." These masterly Discourses, when delivered at the College of Surgeons, elicited the warmest approbation from the distinguished audience. To these may be added the elegant and scientific Lectures

"On the processes of Repair and Reproduction after Injuries," delivered also at the College by Professor Paget; and we have further been enabled to present to our readers Clinical Lectures on various important subjects, from some of the first physicians and surgeons in our metropolis.

In Ethnology we have presented to our readers the profound researches of Dr. Knox, who has, at length, and in his own peculiar style, discussed the all-important question of the "Races of Men." In medicine, we have given the erudite Lectures of Mr. Ross, on "Asiatic Cholera"—a subject of the highest importance at the present moment, and which has drawn from Dr. Turley a series of letters on the saline method of treatment of that disease by Dr. Stevens, whose success has been most remarkable.

The original contributions to the Journal have been from some of the principal Medical and Surgical Practitioners in Great Britain and Ireland, and contain a large amount of valuable experience and practice.

In the Hospital Reports will be found well-selected cases from the London, Provincial, and Irish Medical Institutions.

The proceedings of the Royal Medical and Chirurgical Society, which embraces the *élite* of the Profession, have been regularly given, and the discussions on the various papers read at the meetings reported at length.

In our Editorial Articles, we have not failed to direct the attention of our readers to the higher branches of Physiology, and we have advocated the rights and privileges of the members of the Profession. The injustice to our brethren in the Army and Navy, and to those holding Poor-law medical appointments, has been exposed and condemned; and we have endeavoured earnestly to impress upon the Government the necessity of speedily employing means to check the progress of quackery, so destructive to the lives and health of our fellow-creatures. It is also a source of great satisfaction to us to know that our Editorial Articles in reference to the District Lunatic Asylums in Ireland produced such an impression upon the Vice-regal Government, that it has determined to adopt means by which an efficient medical staff may be attached to every public hospital for the insane.

Whilst thus furnishing our readers with ample Home intelligence, the Foreign department has not been overlooked. In Paris, Berlin, Brussels, and Vienna, we have "our own Correspondents," who have forwarded to us almost weekly the most interesting Professional news from those places, and we are proud to say that our foreign department is unrivaled.

Our reviews of new books have been ample, faithful, and regular; and the Profession has thus been early informed of what has issued from the Press, and of the merits of the authors.

Our Correspondents' letters will be found both interesting and important; and, generally, the Medical News has been published as early as possible.

While the Volume we have just completed contains so much to interest and benefit the Professional reader, in that which we have now commenced we purpose using increased efforts to render the Journal as perfect as possible. Many Original Communications are in preparation for our pages, among which we may name—Dr. Jenner's paper on the Continued Fevers of this Country; a series of Microscopic Observations on Diseases, by an eminent Physician; an Analysis of the celebrated Dieffenbach's Work on Surgery, by Dr. Bushnan. The work of Mr. Wardrop will be completed. The Lectures of Dr. Golding Bird, and of Professors Owen and Paget, will be continued. New courses will be published on Ophthalmic Surgery, with illustrations by Mr. Haynes Walton, Surgeon to the London Ophthalmic Institution; by Dr. Letheby, of the London Hospital, on Toxicology and Medical Jurisprudence; the Lumleian Lectures delivered at the Royal College of Physicians by Dr. Todd; and Lectures on Surgery by Dr. Smith, of Dublin, the author of the celebrated work "On Fractures and Dislocations in the Vicinity of Joints." Some of the most eminent Physicians and Surgeons of Great Britain and Ireland have promised us valuable original communications. We have also made arrangements by which a regular series of Hospital Reports, both British and Foreign, will be given, and our Foreign Correspondents will continue to furnish us weekly with Articles on the progress of science abroad. During the ensuing season, Reports from the different Medical Societies will be published; and in the other departments of the Journal no effort will be spared to give it the highest position which it is possible for a Medical periodical to attain.

PHYSIOLOGY AND MEDICINE.

It cannot escape the observation of even a superficial observer, that, as human science advances, important relations are discovered to exist between inquiries which appeared, at first, to be altogether distinct and isolated. Such inquiries may have commenced at the opposite poles, and may have reference to processes which are apparently altogether unconnected; they may be conducted within the limits of a pin's point, or may range through the boundlessness of space; they may seek to penetrate into the most subtle molecular changes, or may attempt to determine the movement of stupendous planetary masses. But, sooner or later, the hidden links are brought out; the points of mutual contact and impression are elicited; a grand connecting chain is found to bind together all material knowledge; from the most infinite variety springs the presiding unity, and the varied and innumerable phases of material changes shape themselves into the vast generalization of the "Kosmos."

As we penetrate thus into the depths of science, we find each subject partially losing its individuality, receiving impressions more or less profound from kindred inquiries, and imparting to them, in return, something of its own nature. The Geologist thus, after a time, receives aid from the Electrician; the Chemist is led insensibly into the recesses of organized life; and the Astronomer, in recording the revolutions of our planet through space, records the phenomena which affect the health and life of its inhabitants. Throughout nature, we find no isolation and no independence; all phenomena act and re-act mutually on each other. There are many centres of force, but there is none of them whose radii do not reach to the circumference and utmost limit of the material world.

This "connexion of the sciences" becomes evident only after a certain progress has been made. It is not at once we learn that the laws which rule the movements of the planets govern the fall of the apple; or that the electricity which rends the oak may also mould the dew-drop. For the most part, inquiries begin in distinct points, and appear, for a long time, to be isolated and unconnected; then gradually, as their boundaries enlarge, they come within the sphere of mutual influence and reciprocal action.

In this way, ages ago, and while Physiology was as yet unborn, Medicine had attained a considerable development. It was built on its individual basis, and was comparatively unaffected by its cognate sciences. But this is the case no longer. Empirical medicine has lost its distinctive characters, and the Physiology of Health is becoming amalgamated with the Physiology of Disease. In some former articles on this subject, we alluded to this fact, and to the profound impression which the practical part of our art is receiving from the Physiology of the present day. It is in vain to deny the reality of this influence; it would be fruitless to attempt to conceal it. Let us accept it as a fact, examine into its extent, and attempt to estimate its further progress.

Empirical Medicine is independent altogether of Physiology. Hippocrates, Avicenna, Aretæus, or Rhazes did not the less record the beatings of the pulse, because they were ignorant of the circulation of the blood. This was a physiological fact which at once rendered clear much of what had previously been but vague surmise. We have now become so accustomed to Harvey's great discovery, that we forget it is not intrinsically a part of Empirical Medicine, although being true, no sooner was it proclaimed, than it united itself indissolubly with Medicine, the facts of which it helped to explain and correct.

We might take up this subject from the commencement, did not its extent utterly defy our limits. To trace the gradual progress of true rationalism must not be our aim; we must content ourselves with considering what is the product of our own time, and the distinguishing characteristic of this period of science.

Perhaps the three most special bonds of union which have arisen in the present day between Physiology and Medicine, are derived from the investigations into the nervous system, from the inquiries into the origin of the tissues, in which has originated the beautiful theory of Cytogenesis, and from the researches into the molecular chemical changes of the living body.

It is not too much to say, that, without the pure physiological investigations into the functions of the nervous system, experience could never have unraveled the infinite perplexities which surround the study of the diseases of this portion of the frame. Empirical medicine, in order even to record its facts precisely, must have created a rude Physiology, and have deduced from morbid conditions an estimate of

the normal functions of the several parts of the nervous centres. Even now, much remains dark and obscure; but strike out, this moment, our knowledge of the functions of the nerves, of the true spinal cord acting independently of volition, of the various commissural interlacements of the encephalon, the cord and its offshoots, and this darkness and obscurity would be increased tenfold. Abandon the clue which the beautiful researches of the modern Neurologists have given as a guide through the labyrinth, and the best recorded case of nervous disease becomes a series of meaningless facts, devoid of significance, because deprived of the light which alone can reveal their intimate connexion. And, as Physiology has done so much for Medicine in this department, so now the observations of the Physician are adding daily to the facts of Physiology, giving, as it were, light to that from which again light is reflected upon it. And daily we have fresh evidence, that the many curious phenomena presented by diseases of the nervous system are all shortly to find their appropriate places, and to be arranged under comprehensive laws.

The same remarks apply to the microscopic investigations into minute anatomy. How evident it is that physiological investigation must determine all normal forms of growth, before the Physician can inquire into the abnormal, or can even rightly say what is abnormal. Here empirical medicine must always be imperfect. Of what limited use have been the innumerable treatises on Cancer which were published in the first forty years of the present century! Cancer COULD NOT be investigated until we were able to apply to it the tests which should compel it to reveal its origin, the mode of its increase, the peculiarity of its manifestation. Microscopic Anatomy and the chemistry of molecular matter, have, within the last twenty years, done more to indicate to us the true nature of Cancer, than the observations of all the Physicians since the time of Galen. So deeply do we feel the importance of minute Anatomy to practical Medicine, that we have made special arrangements to bring under the notice of our readers the fullest information on this subject.

And again, in like manner, Organic Chemistry is daily becoming more and more medical. Medicine is daily becoming more and more chemical. But as yet the rich mine has hardly been opened; we have not yet discovered more than a few of the surface veins, and even these may have led us away from the main deposit. But the facts, we already know, have proved to us the richness of the soil which produced them. Let us adduce one of the simplest and easiest which occurs to us. The determination of the characters of albumen, and its habitat in the body, are pure chemico-physiological facts. But when albumen appears in the urine, and is chemically recognised, this fact at once appertains to practical medicine,—and what an important fact it is, we need not indicate. We need only say, that it is hardly conceivable how, without a knowledge of the series of phenomena included under the comprehensive term of albuminuria, the older Physicians could have had any true conception of a most extensive and common class of diseases.

But we must reserve any further remarks on this head for another opportunity. The subject is too extensive to admit of any but a superficial survey; even this, however, will not be without abundant fruits.

NEW MEDICAL CURRICULA.

THE authorities of the College of Surgeons and of Apothecaries' Hall have just published an amended curriculum of study, which will be required of all those whose attendance on Lectures shall commence on and after the 1st of October, 1849. The number and length of the Sessions remain as heretofore.

To refer to the several chief alterations made, the first is the transference of the course of Lectures on Materia Medica from the first winter to the first summer session,—a manifest improvement, and one the adoption of which has oftentimes been urged by several valid arguments. The labours of the student, during his first session, are, therefore, now much lightened; instead of having to attend, as under the old two-year course of study, to some five or six different subjects, he has but to divide his time and attention among the three subjects—Chemistry, Anatomy, and Physiology. But he is made to work harder during his first summer session; the amount of labour being now more equally distributed over the academical year, for, not only is there tacked on to the course of Botany (the only one hitherto insisted on in the first summer session) that of Materia Medica, but the Lectures on Midwifery are also appended. Further, the regulations of the College here chime in, making it necessary that the student attend, during his first summer, the surgical practice of his hospital. And it is to be observed, that it is on the requirement, that the Lectures on Materia Medica and Midwifery be attended during the summer, that the College regulations have been modified and made to coincide with those of the Hall.

The summer prospects of the Medical Student are hence much blighted: he can no longer date upon the leisure of the long summer days, and busy his mind with concerting plans for enjoyment when the short hour of the Botanical Lecture is over. No! what with three courses of Lectures and Hospital Practice, his time will be otherwise occupied.

But, as a set-off against this dark side of the picture, the student must bear in mind, that his winter labours have been lightened, that Materia Medica will no longer perplex him at the outset of his student's life, when as yet ignorant of the collateral sciences, Chemistry and Botany, which of themselves constitute its chief part, and that the call to attendance on Midwifery Lectures will not interrupt him from his engagements in the dissecting room and hospital during his second winter's study.

Lectures on Midwifery, again, form part of the second summer session; and during this period, likewise, attention is to be paid to Practical Chemistry, not nominally, but in fact, for the regulation remarks, that "by practical chemistry is intended a specific course of instruction in the laboratory, with an opportunity of personal manipulation in the ordinary processes of chemistry, and of acquiring a knowledge of the various re-agents for poisons."

The advantage of being enabled to pass the Latin Examination at Apothecaries' Hall, antecedently to the final general examination, is again extended to students when they have completed two winter sessions of their Medical studies, and not, as formerly, at any period subsequently to their first registration.

The only remaining innovation in the regulations of former years to be enumerated, is one introduced by the Council of the College of Surgeons, which evinces a spirit of liberality towards our Colonial Schools, and those individuals, now becoming numerous, who receive part of their Medical education at them. It is a measure, indeed, calculated to sustain the influence of the College in our Colonies, and to preserve them from the inroads of unqualified, or but partially qualified, Medical men.

It enacts, that "Candidates who shall have attended at recognised Colonial Hospitals and Schools, the Medical and Surgical practice and the several Courses of Lectures, with the demonstrations and dissections required by the foregoing regulations, will be admitted for examination upon producing certificates of such attendance, together with certificates of having attended in London, during one winter session, the surgical practice of a recognised hospital, and Lectures on Anatomy, Physiology, and Surgery, with demonstrations and dissections;" and that the recognition of Colonial Hospitals and Schools be governed by the same regulations as those in the provincial towns of England.

The several alterations in the prescribed course of Medical study above detailed, are, in our opinion, in the right direction, calculated to benefit the student, and to secure a better attention to the more important ones—viz., Hospital Practice and Practical Anatomy. For his mind will not be so distracted by the multitude of Lectures he is called upon to attend during his winter Sessions, as happened under the late regulations, when, if a Student desired to be conscientious in attending the prescribed number of Lectures, it entailed on him the necessity of neglecting the dissecting-room and hospital.

But, by the way, we ought to have observed, that the governing bodies have ceased to specify the number of Lectures incumbent upon the several Lecturers to deliver in their respective courses. This, again, is an important feature; and we hope the Teachers on some subjects will take advantage of it to abridge the number of their Lectures, and thus save the Students the toil of attending so many hundred in a season, as they have hitherto been called upon to do. For it is generally admitted that little real good is to be gained by several of the systematic courses prescribed. On the other hand, we are glad to see Clinical Medicine and Morbid Anatomy put more prominently forward in the scheme of study of the Apothecaries' Company; and we hope those important topics will henceforward not meet with the neglect they have hitherto experienced, but be really and practically made integral parts of Hospital instruction.

MEDICAL INCOMES AND THE "TIMES" NEWSPAPER.

The *Times* newspaper, in a late article on the amount of the Income-tax, infers that the members of the Medical Profession have, with others,

fraudulently concealed the amount of their incomes. Anything which concerns the honour of our brethren is a matter of great interest and importance. The charge creates general indignation; for bad as taxes are, dishonesty is worse. The accusation, which few can have failed to notice, refers to the Income-tax Schedule D, under which the profits derived from professions, occupations, and trades, are required to be entered. Unfortunately, the Medical and the other learned professions, are mixed up in the returns with persons engaged in every kind of profitable vocation throughout Great Britain. And if the professional classes, whose characters constitute for the most part their stock in trade, feel confident, as we trust they do, that the charge does not justly lie against them in any such degree as to affect the general mass, they would do well to unite in getting the particulars of their dealings with the Income-tax Commissioners stated separately in any future returns, like those lately made to the House of Commons. As regards the Medical Profession, we are satisfied that the charge is groundless. Indeed, we even doubt if it applies to any class. The leading journal has not acted with ordinary fairness towards the accused parties. It judges the case without taking the trouble to ascertain the facts. We do not pretend to say that there may not be many persons in Britain, deriving income from a vocation, who have made no return at all; but looking to the aggregate of the returns under Schedule D, and comparing that with the calculated total of the incomes, as far as indicated, we think there is but small ground for the charge of fraudulent concealment anywhere. The writer in the *Times* states the number of persons giving returns under this schedule, namely, nearly 150,000 (147,659), but he has not been diligent enough to cast up the corresponding amount of income. On a fair calculation it is seventy millions—that is, something short of 148,000 persons engaged in professions and occupations return an annual income of seventy millions. And after a deduction on account of incomes below 150*l*., there remain nearly 113,000 persons taxed on an annual income of sixty-six millions—a sum equivalent to an average of not much less than six hundred pounds annually to each, the Income-tax on which is not much below two millions, or considerably above a third part of the total proceeds of that tax. It is a fact to be remembered, that nearly two millions annually are deducted from the hard-earned wages of those who labour, not with their hands, but with their heads. But the classes of the community referred to, and particularly the Professional classes, are far from being able to live as they do, and to keep up that show of wealth and comfort which appears on the surface from the mere wages of their labour. In so far as there is the reality of that wealth and comfort, it is, in a very great degree, dependent on their being entitled to draw a part, and often a great part, of their expenditure from lands, houses, shares of stocks, &c., the proceeds of which come to them already diminished by the shears of the tax-gatherer. Thus, the writer in the *Times* has fallen into error from two causes: first, by taking the mere *prima facie* view of the case, and neglecting to make an exact estimate, from the table in its columns, of the actual proportion which the apparently smal number of comfortable incomes derived from Professions, occupations, &c., bears to the aggregate of incomes charged under the tax in question; and, secondly, by omitting to take into account how many of the class giving returns under Schedule D, are possessed of means yielding part of their income, but charged under other Schedules.

The *Times* takes the whole number of the Medical Profession in Great Britain at upwards of twenty thousand, or at about one-seventh of the persons assessed under Schedule D. And how well off would our brethren account them selves to be, if they drew annually from the country ten millions, that is, one-seventh of the seventy millions which the *Times* assumes to be so paltry a sum to represent "the aggregate earnings of the Professional and mercantile classes of Great Britain! This sum would give 500*l*. a-year to each of the twenty thousand. Strike off the twelve millions which represent the larger incomes, such as medical earnings hardly reach, and there will still remain enough to afford an average of nearly 414*l*. annually to each of the twenty thousand. Even this average is far beyond what the Medical Profession can command. And this view, so it appears to us, settles the question as regards the groundlessness of the charge against our Medical brethren.

MEDICO-LEGAL INVESTIGATIONS IN SCOTLAND.

An incident occurred last week in the Edinburgh Infirmary which deeply touches the rights of our Scottish brethren, though, if such grievance could take place in England, it would be under a different form. A boy died, after having been ten days in the Infirmary, under the care of one of the ordinary Physicians. The case was one of the greatest interest—dropsy, involving disease of the heart, brain, and kidneys. The inspection next day was looked forward to with much curiosity by Physician, Pathologist, and pupils. In the interval between the death and the usual time for inspection, two strange Surgeons arrived at the Infirmary with a warrant from the Sheriff, and proceeded to examine the body with closed doors, having made no communication to any of the Medical Men before concerned in the case. Great was the disappointment when this act of authority was announced next morning; but, on the supposed relicts of the body, in a kind of despair, being brought to the table, it was found that nothing more had been done than to open the chest, make a few cuts in the lungs, without taking them out, and carry away the heart. Great wonder arose as to what the Sheriff could mean by sending a warrant to steal a poor boy's heart; and the only rational conjecture that has been made to this hour is, that a rumour had got up, that cruelty under the Poor-law had broken the boy's heart before he was brought to the Infirmary, and that the Sheriff wished to convince himself of the contrary by ocular inspection. The heart, on being demanded, was sent back two days after.

Now, this is a very absurd proceeding; and we cannot think that any Scotch authority, great or small, could knowingly countenance such manifest discourtesy, unless the case had been one of the most urgent necessity. What keeps up such occurrences as this is neither law nor reason, but an extraordinary notion, that the examination of a dead body for judicial purposes should be conducted with no one present but those named in the warrant. On the contrary, no two Medical men should ever take on themselves the responsibility of examining a body without medical witnesses, if such be within call—for which many reasons will at once suggest themselves. What though authorities forbid it, there is no law to prevent such witnesses being taken. Medical men should insist on the right and necessity of having such witnesses, in case their report be called in question. It is not long, however, since one of the Scotch Judges, with less wisdom than becomes the Bench, reprimanded an accoucheur for having taken with him, to such an inspection, a very eminent brother, whose name was not in the warrant. We fear such reprimands must be borne till reason overcomes prejudice.

THE CHOLERA IN BLACKFRIARS.

Some six months ago, when the Commissioners of Sewers met to elect an officer of health for the City, some of the candidates were "snubbed," for having made statements reflecting upon the Drainage of London within the walls. Even Mr. Simon was in danger of being rejected, in consequence of a rumour that he had said something unfavourable to the City sewerage. An energetic denial, however, appeased the wrath of the Commissioners, and he was fortunate enough to obtain a majority of their votes. Since then the Asiatic pestilence has been carrying off its victims in different parts of the Metropolis; but it was satisfactorily announced, from time to time, that there was "no cholera in the City." Within the last fortnight, however, the disease has made its appearance in the parish of St. Ann, Blackfriars, a neighbourhood where it committed great ravages seventeen years ago. It has now been discovered that the sewerage here is anything but perfect, and that many of the houses in the bye-streets and lanes are in a most filthy condition. It appears, that, in Water-lane, within a distance of 500 feet, there are twelve gulley holes and six air vents in a direct line, besides others at the end of Printinghouse-lane and Playhouse-yard,—that these gratings, not being properly trapped, allow stench and steam to escape to an extent which renders the whole neighbourhood infectious. The houses of the poor in this locality are now found to be crowded with human beings, and from the wretched state of the dwellings, and the filthy habits of the inmates, fatal diseases are engendered.

It is singular that these discoveries were not made before Cholera invaded the place. In Water-lane we have the Hall of an English Medical Corporation; in Printing-house-square, the Establishment of the Daily *Times*. It is remarkable that the Corporation Medical and the Corporation Typographical should have remained ignorant of this state

of things till cholera brought it to their knowledge. We suppose, however, that th aroma of drugs prevented the apothecarie from scenting the sewers, and that the force o habit so far acted upon the olfactories of th officials connected with the *Times* office, tha they were only capable of smelling from afa the pestiferous exhalations of stagnant ditche and ill-constructed sewers. We have heard o certain individuals who have been "long-sighted" and "long-winded," but not till now of any having been "long-scented." The olfactories of the *Times*, however, appear to be incapable of recognizing the strongest emanations close under its nose, while they are acutely sensible of stenches a hundred leagues off.

We hope, that now the nose of Jupiter Omnipotens has been directed to the nuisances which surround his Palace, he will use his power to have them removed. We would remind him that, in a passage called Church-entry there is a grave-yard gorged with putrefying animal matter; that the surface of this Golgotha is three or four feet above the level of the footway; and that the back windows of a number of houses, said to belong to the Apothecaries' Company, open directly upon this yard; that the houses themselves are in a most wretched condition, and are crammed with lodgers. The frontage of these dwellings is in Fleur de lis Court, a *cul de sac* into which the air and light of heaven obtain but a very limited admission. We have strong doubts whether this Court is favoured with a sewer, and we believe the cloacæ are cess-pools in the cellars, from which a most offensive effluvia continually arises. We trust that some one from the *Times* office will make a survey of these premises, and that Mr. Simon and Mr. G. A. Walker will also visit the place. Unless somethingbe immediately done the inhabitants will be decimated with fever or cholera.

The suggestions, also, of Mr. Simon to the Court of Sewers ought to be forthwith acted upon. They are as follow:—

1. The organisation of a preventive medical staff, having for its duty to inquire into the existence of premonitory symptoms of cholera among all that poor and ignorant population who would be uninformed of the great importance of checking such symptoms.
2. Arrangements for the relief and reception of the sick, in the event of their number becoming larger than the existing establishments could readily and certainly accommodate.
3. Arrangements for the relief of our crowded houses or infected localities, and for the deportation of those persons, particularly children, who may be showing preliminary symptoms of cholera, or may otherwise be drooping in health from exposure to injurious local influences not immediately removable.

DR. STEVENS' SALINE TREATMENT OF CHOLERA.

A CORRESPONDENT has lately addressed to us a few remarks respecting the favourable opinion which we have expressed of Dr. STEVENS' Saline Treatment of Cholera. Our Correspondent takes two special objections to our opinion, 1st, that the evidence in favour of the practice is insufficient; 2nd, that saline medicines are not taken as such into the circulation, but undergo transformation in the stomach. With regard to the first objection, the estimate of this value of the saline over all other means of treating cholera, must be formed by each man for himself. We have placed before our readers much valuable testimony on the point; testimony which has had great weight with us, and which has led us to form a most favourable opinion of the success of the practice. But, of course, we do not desire to bind our readers to our opinions, and we only hold our opinion provisionally, until future observation shall confirm or disprove it. As to the second objection, we confess we do not understand our Correspondent. Whether a saline medicine shall undergo decomposition in the stomach or in the tissues of organs to which it is carried by the torrent of the circulation, depends upon the nature of that medicine. Some are decomposed; others can be detected passing off unchanged through the medium of the skin or the kidneys. In the saline treatment of cholera, the object is to supply to the blood certain salts, which are presumed to be deficient in that fluid, such as chloride of sodium, and phosphates of soda or potash. These salts, as far as we know, are absorbed at once, and unchanged, into the circulation, and then, it is presumed, exert on the organic principles of the blood a chemical influence similar to that exerted by the normal salts which had been thrown out from the system under the influence of the disease.

THE COLLEGE ELECTION.

A very numerous attendance of Fellows took place on Thursday afternoon, in the College Theatre we should say as many as 200 were present), for the purpose of electing three Members of Council. The proceedings commenced, on the President taking the Chair, by stating the objects of the meeting, and calling on the Secretary to read those portions of the Charter and Bye-laws having reference to the Elections, which having been done, the Secretary read the names of the various Candidates from the chronological list, and, on coming to Mr. Hodgson, late of Birmingham, Mr. Partridge proposed, and Messrs. Soden and Bowman seconded, that gentleman as a Member of Council. M Luke, of the London Hospital, and retiring member of the Council, the next name n order, was proposed by Mr. Macmurdo of St. Thomas's Hospital, and seconded by Messrs. Kingdon and Paget. On reading the name of Mr. Thomas Wormald, of St. Bartholomew's Hospital, Mr. Guthrie, the former President of the College, nstantly rose, and in a very significant manner, and amidst great silence, proposed that gentleman as a very fit and proper person to occupy a seat in the Council, a proposition that was immediately seconded by Professors Owen and Paget. The names of the candidates having been attached to the balloting boxes, the voting commenced; and, at the conclusion, the President stated the result to be— Mr. Hodgson, ayes, 153; noes, 23. Mr. Luke, ayes, 162; noes, 15. Mr. Wormald, ayes, 133; noes, 44. Thus, by a majority of 89, has this gentleman so signally defeated his enemies.

As indicative of the feelings of the "*Fellows*" towards the "John Hunter Club," we may mention that many of them attended from Birmingham, Manchester, Exeter, Barton, &c.

It was stated, that the "Club" consists of forty eight members; so it would appear that these very exclusive gentlemen not only are devoid of interest, but entertain opinions totally at variance with the great body of the Profession.

REVIEWS.

Parturition, and the Principles and Practice of Obstetrics. By W. TYLER SMITH, M.D. London. Lecturer on Obstetrics in the Hunterian School of Medicine. Pp. 395. London: Churchill, 1849.

Dr. Tyler Smith is a clever man. He has published a very fair volume on scrofula, and, if report does not deceive us, he has written many an able "leading article;" and now, taking as his basis the views of Dr. Marshall Hall, to whom his book is dedicated, he has brought out a very amusing, and, to a certain degree, instructive volume, on "Parturition, and the Principles and Practice of Obstetrics." But it is not a volume which will displace the more practical works of Rigby and Ramsbottom; and the lectures which it contains—twenty-six in number—must be regarded as physiological commentaries on so many important points in obstetric science, rather than as constituting a treatise on practical midwifery.

The introductory lecture is principally devoted to the differences of obstetric practice in this country and in France, which Dr. Smith attributes more to religion than to the social states of the two countries. Although the lecture concludes with the laudable observation, page 11, that "we must not let even electicism steal away our *principles* and springs of action, which must be held to without bigotry but firmly," we can hardly feel that our Author acts up to this doctrine, when we find him telling us, in an earlier part, page 7, that "freedom of examination, though productive of some good in a diagnostic point of view, is carried to such an extent of indecency in the French Hospitals, as to make medicine the ally of immodesty and demoralization, rather than of decency and of virtue;" and adding, that "it would be difficult to say whether the indecent and public exposure of their women inflicted a deeper wound on the modesty of one sex or the morality of the other."

The sixth lecture contains a very good account of the ovular theory of menstruation; but we must enter a very strong protest against the introduction, in elementary works such as Mr. Churchill's Manuals are supposed to be, of such passages as the following. At page 83, Dr. Smith states, "the theory of menstruation was very much ridiculed when first propounded by Dr. Power. Its Author was treated as a visionary, and I have heard he acquired among accoucheurs the name of 'Menstruation Power.' His little book was severely scourged by the critics of that time; but the event is another proof, that whenever ideas of sterling worth are put forth, the world, even if it do not at once appreciate their value, is sure to find them 'after many days.' Dr. Power himself seems to have been little careful about the result; he never appears to have discussed the matter, or even resorted to experiments; but to have calmly thrown his ingot of gold into the stream of time, there to be refined, instead of casting it into the burning fiery furnace of controversy, for that more rapid assay which original minds sometimes covet. Very recently I paid a visit to him, at his residence at Westminster, *and I am proud to say, he was much interested in my own researches in the physiology of Parturition.* I found him amusing himself with painting and composition. He showed me some geological landscapes, if I may so term them, from his pencil, the still-life and figures of which were composed from the study of geological strata and fossil remains; icthyosauri, plesiosauri, and other monsters basked, or pursued their prey, in scenes belonging to a primeval world. I mention this to show the original turn of the mind to which we owe the true theory of menstruation."

We regret that Dr. Smith should have penned this paragraph, and, in the sentence we have marked in italics, allowed his good sense to have fallen into abeyance, or, like Sebastian, "let fancy still his sense in Lethe steep." It would have been more seemly, if he had followed Dr. Power's example, and "calmly thrown his ingot in the stream of time." But there seems a sort of fatality among the "Marshall Hall and Robert Lee" school of physiologists, by which the besetting sins of those

two eminent men—failings which we are convinced have, in a great measure, been the cause of the opposition their views have experienced—seem, as a matter of necessity, to extend to their more immediate followers.

If Dr. Smith's volume did not contain much valuable matter on many physiological points, we should deem it a waste of time and labour to notice the serious faults with which it also abounds. Who can read the following sentence without regret? Who, ignorant of Dr. Smith's real physiological knowledge, will place confidence in his other statements, when he reads at page 117:—"The pains of natural labour are hard to bear, though of late they have been most cruelly exaggerated by interested parties; but they ennoble the sufferer morally, and, after the trial has passed, there comes the cry of her infant as a happy crown to the maternal martyrdom. . . . . On a former occasion I pointed out, that in women, to whom ether vapour had been administered during parturition, the sexual orgasm had been substituted for their natural pains—an exchange which women of modesty would far more shrink from, than the liveliest agony. Under chloroform, too, I have been informed of instances in which the lying-in-room has been defiled by the most painful and obscene conversation."

We are at a loss to understand to what "interested parties" Dr. Smith alludes; we can conceive none but the druggists who sell ether and chloroform, and we do not remember that any of these have "exaggerated" the pains of labour, or even described them; and as for the moral objections to the employment of anæsthetics in the lying-in room, we find that Mr. Gream (*Remarks on the Employment of Anæsthetic Agents in Midwifery, by G. T. Gream*, 1848) is the only accoucheur who can afford personal evidence regarding the aforesaid class of conversations. It would be interesting to ascertain if they were especially noted to have occurred in the confinements of the ladies to whom that gentleman afforded much relief by his "vaginal dilator," as described in his recent and very curious paper.

We should not have felt justified in recommending Dr. Smith's volume to our readers without pointing out some of its defects; but nevertheless we *do* recommend it; and we, therefore, hope to be included among the "candid persons," described in the Doctor's Preface, who are willing to admit that he has "both added to reflex physiology, and made extensive applications in practice, which had eluded previous observers."

On the Extraction of Teeth, with an Account of a New and much less Painful Mode of Operating. By Henry Gilbert, M.R.C.S.L.

We have much pleasure in directing the attention of the Medical Profession to this pamphlet. The subject of which it treats is of great importance. Every discovery that tends to diminish pain, is an invaluable boon to humanity, and it would be unjust to withhold this praise from the invention of Mr. Gilbert. We speak from a personal knowledge of its advantages, and have no reservation in the assertion, that it will ultimately supersede the clumsy, uncertain, acutely painful, and often dangerous means employed in the extraction of teeth. We do not wish it to be understood, that he renders the operation pleasurable. He deprives it, however, of much of the immediate and consequent suffering, almost inseparable from the use of the key and forceps, as at present used; and, in contemplating the simplicity and efficiency of his contrivance, the question forces itself on our consideration—Why was it not suggested before? This, in reference to any invention, is the highest compliment that can be paid to it. It is the involuntary approbation of common sense.

Mr. Gilbert, from a just appreciation of the value of his invention, and from a determination to carry it into effect, has sacrificed a large and lucrative practice, and we believe and hope wisely. The prejudices opposed to whatever is new, and the interests and reputations occasionally affected by it, may possibly, for a time, retard the acknowledgment of his scientific claims, and the usual reward which should ever accompany them; but he may rest assured that it can be only for a brief period.

The following is his description of the instrument and of its advantages:—

"My object was," he remarks, "to obtain a fixed fulcrum, external to the mouth, on which, during the extraction of the tooth, the instrument would rest, and thus obviate the difficulties and objections connected with the instruments in general use. The chair which I use is an ordinary easy chair, with a back that can be inclined to any angle, the top of which is semi-cylindrical, for the reception of, and to enable the operator to come close to the head of the sufferer. At the right hand side of this chair there is fixed a strong steel bar, or stem, on which, again, there is a socket capable of sliding on it, and of being fixed at any required height, by means of the set-screw, which, on being turned, presses the piece against the stem. The moveable bar, which is thus capable of being raised or lowered at will, holds another piece of steel, or arm, placed horizontally to the chair, which again holds a third piece of metal, the latter being the fulcrum on which the extracting instrument rests.

"The teeth are extracted by means of the ordinary forceps, adapted to the fulcrum, in the following manner:—The operator first causes the person to recline back in the chair, and adjusts the bearing, so that it will come between the jaws, (when a back tooth is to be extracted;) he then takes hold of the tooth with the forceps, which will rest on the bearing, if a lower tooth is to be extracted, and by moving the forceps upon the bearing as a fulcrum, he lifts the tooth out of the lower jaw. If the tooth is to be extracted from the upper jaw, the forceps are introduced below the bearing, and act so as to draw the tooth downwards out of the jaw."

The great advantages of this instrument over the present method of extraction are—

1. Impossibility of fracturing the jaw-bone.
2. The gums cannot be torn or lacerated.
3. The gums are not pressed upon by the instrument.
4. A large amount of pain is saved.
5. The great danger of breaking the diseased tooth avoided.
6. Little or no bleeding takes place.
7. The adjoining teeth cannot be injured.
8. The teeth are extracted perpendicularly, or in the line of their axis, the instrument being used entirely independent of the gums, teeth, or jaw.
9. The patient is able to masticate his food almost immediately after the operation.

Mr. Gilbert has also described a new form of claw to be used by the aid of the external fulcrum for the extraction of stumps.

Excellent as the pamphlet is, it has two faults we should like to see corrected—its size and price. What is intended for mankind at large—for the alleviation of human suffering, should not necessarily be small in bulk, but it is desirable that it should be cheap, so that the benefits it is calculated to confer may be brought readily within the reach of the many. We would, in fact, suggest to Mr. Gilbert the propriety of condensing the contents of the pamphlet, if not to one-fifth of its present size, at least to an extent that would enable him to reduce the price in that proportion—an alteration that would not be less advantageous to himself than the public.

Pathology of the Human Eye. By John Dalrymple, F.R.C.S. Fasciculus II. London: John Churchill. 1849.

Mr. Churchill's illustrated works are among the best that emanate from the Medical Press; and Mr. Dalrymple's illustrations of the Pathology of the Human Eye will take a high rank among the many books dedicated to the diseases of that important organ. We have not received the first part of the work before us; but, judging from the second, we are inclined to suppose it worthy of the highest praise. Part II. contains four plates—5 to 8—illustrative of nineteen varieties of eye disease. We have examples of warts, horns, syphilitic and malignant ulceration of the lids, diseases of the lachrymal apparatus, ecchymosis, œdema of the eyelids, vascular diseases of the eye, as conjunctivitis, and scrofulous ophthalmia. As regards the descriptive letter-press, we conceive it to be as accurate as the illustrative drawings; and, were the price less, we doubt not it would become as much in vogue among practitioners as Mackenzie's work on the same subject. We strongly recommend it; for, although the price is high, it is above price to the country practitioner, obliged, by the circumstances in which he is placed, to depend upon his own resources, and, in eye cases, to act often immediately, and that without the advice and assistance of the professed oculist.

DR. ARNOTT ON THE THERAPEUTIC AGENCY OF EXTREME COLD OR CONGELATIONS.

[To the Editor of the Medical Times.]

Sir,—In my little work on the remedial use of severe cold, which was noticed in the last number of the *Medical Times*, there is a deficiency or want of explicitness in the exposition of the subject, which a statement of the reviewer induces me to supply without delay. He says, that "from one to three minutes will be ordinarily sufficiently long to effect the congelation." The skin is congealed by the direct application of ice and salt generally in less than half a minute; but if the reviewer mean the period of congelation, it ought to be understood, that in headache, the disease principally treated of, I seldom keep the net containing the frigorific in contact with the skin many seconds longer than is necessary to cause congelation, or hardness and whiteness; it is usually shifted to another part almost immediately on this appearing, although I sometimes re-apply it to a portion of the skin, which has already been congealed, on the disappearance of the whiteness. In erysipelas the net may be moved to and fro, or the surface may be brushed by it, as it were, keeping the cold just one degree above what will cause congelation, in order to prevent the little smarting or sense of dragging which this effect produces. A stronger application would, doubtless, be often more efficient in headache, and render a repetition of congelation unnecessary; and it is not from fear of injuring the skin that I do not usually make it stronger; but I am unwilling in applying severe cold to so conspicuous a part as the forehead, which is the portion of the scalp usually congealed, to cause greater redness of the skin than what cannot be avoided. If the cold be applied for the short period mentioned, there is seldom any redness remaining after twenty-four hours. The application of congelation to the scalp for several minutes, as was lately made to the whole scalp, (and with excellent effect in a case of meningitis,) will produce a redness of several days' duration.

I may be permitted, before concluding the subject, to say a few words in vindication of my having attempted to explain the *modus operandi* of congelation. I at once admit the justness of the critic's observation on the hazard of preventing, in some cases, the employment of a remedy, by giving an explanation of its action which may be deemed a fallacy, and so prejudice a practitioner, who would otherwise apply it. On the other hand, unless the Practitioner considers a newly proposed remedy to be a rational remedy; or, in other words, unless he thinks it is likely to produce certain physiological changes which he may consider necessary for the cure; or unless it bear an analogy to other remedies which he acknowledges as such in analogous affections, he is not likely to employ it at all; but, on the contrary, to suppose that the proposer or inventor has, by wearing the distorting spectacles too often worn by inventors, himself been deceived. Now, I think, that the explanation I have advanced, which do not dive too far into the mysteries of the subject, will obtain general assent. That it will obtain universal assent it would be absurd to expect, considering the very unsettled state of opinion on the nature of inflammation, or the morbid condition of which congelation is the proposed remedy. But those who take other views of the matter may still find in congelations what is consonant to their notion of what is required. If, for instance, they think that there is too little action in the inflamed part, and that debility and obstruction constitute the principal morbid elements, they may be induced to try congelation from the idea that it may stimulate, and by its completely emptying the vessels (which the perfect whiteness produced manifestly shows it does) they may consider it a valuable deobstruent. In page 32 of my pamphlet on Cold, I have expressed the little importance I attach to reasonings on the *modus operandi* when com-

pared with the facts which I relate; and I feel a little surprised, after warning against the mischiefs of theory in my previously published Essay on Therapeutical Inquiry, and stating that almost the only useful purpose it has as yet served is to direct attention to valuable remedies, to find that I have incurred an imputation of endangering a good practice by a bad, or, at least, by a questionable theory.

These observations apply to the explanations which I have attempted of the action of congelation in suddenly subduing every inflammation that is accessible to it. Of its no less remarkable action in nervous affections, and in prurigo, impetigo, and other distressing diseases of the skin, I have offered no explanation; conceiving that the very imperfect means we now possess for remedying these affections, in which the natural tendency to cure is not so manifest as in inflammation, and the universally known benumbing quality of congelation, would be quite sufficient, so far as they are concerned, to induce an immediate trial of it.

I am, Sir,
Your most obedient servant,
James Arnott.

Brighton, June 29th, 1849.

[We are glad that our remarks have induced Dr. Arnott to state, a little more explicitly, his own mode of applying cold to the head; in order to avoid misunderstanding we used as nearly as possible his own words. We never entertained a doubt that Dr. Arnott supposed his explanation of the *modus operandi* of congelation very good, nor that he was convinced that his explanation would meet with general assent: propounders of theories are generally satisfied with the excellence of their own reasoning: all we expressed a doubt concerning was, the satisfaction the Profession would derive from his explanation. How the action of a remedy in curing a disease is to be explained so as to obtain general assent, when opinion concerning the nature of that disease is confessedly in an unsettled state, we own our inability to comprehend.—Ed. *Medical Times.*]

THE WEATHER AND THE LEECH.

[To the Editor of the Medical Times.]

Sir,—In Hayley's "Life of Cowper," we find a letter addressed to Lady Hesketh, in which the poet acquaints Her Ladyship with this interesting fact, at the close of the epistle:—"Yesterday it thundered, last night it lightned, and at three this morning I saw the sky as red as a city in flames could have made it. I have a leech in a bottle that foretells all these prodigies and convulsions of nature. No, not as you will naturally conjecture, by articulate utterance of oracular notices, but by a variety of gesticulations which here I have not room to give an account of. Suffice it to say, that no change of the weather surprises him, and that, in point of the earliest and most accurate intelligence, he is worth all the barometers in the world. None of them all, indeed, can make the least pretence to foretell thunder, a species of sagacity of which he has given the most unequivocal evidence." Taking these few remarks as my text, you will find the following observations accurate, and, if you deem them worthy of a place in your Journal, I shall be obliged to you to have them inserted:—

1. If the weather proves serene and beautiful, the leech lies motionless at the bottom of the glass, rolled together in a spiral form.

2. If it rains, either before or after noon, it is found crept up to the top of its lodging, and there it remains until the weather is settled.

3. If we are to have wind, the poor prisoner gallops through its limpid habitation with amazing swiftness, and seldom rests till it begins to blow hard.

4. If a remarkable storm of thunder and rain is to succeed, for some days before it lodges almost continually without water, and discovers uncommon uneasiness, in violent throes and convulsive-like motions.

5. In the frost, as in the clear summer weather, it lies constantly at the bottom; and in snow, as in rainy weather, it pitches its dwelling upon the mouth of the phial.

6. Perhaps it may not be amiss to note, lest any of the curious should try the experiment, that the leech was kept in a common two-ounce phial about three-fourths filled with water, and covered with a bit of linen rag. In the summer, the water is changed once a week, and in the winter, once a fortnight. This is a weather-glass which may be purchased at a very trifling expense.

These observations have hitherto been confined to the weather; it has occurred to me, however, that epidemics, cholera, influenza, fevers, may be predicated by the instincts of this curiously sensitive creature; and I am now arranging a series of experiments, which will test the powers of my intelligent friend in so desirable a prognosis.

I do not pretend to offer any theory or explanation of the curious facts above stated; I only cast them upon the waters, in the hope that some naturalist with more leisure and ingenuity than myself, will perhaps, after many days, enlarge and apply them to some beneficial purpose; one suggestion only will I offer in explanation—Is it the electrical condition of the atmosphere that produces the curious habits in the leech?

I am, Sir, your obedient Servant,
William Hooper Attree,
Formerly House-Surgeon to the Middlesex Hospital.

9, New Cavendish-street, June 27, 1849.

MEDICAL REFORM.

[To the Editor of the Medical Times.]

Sir,—I quite agree with your suggestion as to the necessity of petitioning the Legislature to consider the question of medical reform, during the present session of Parliament; and I think, with your correspondent, that a Petition emanating from yourself and a copy published in the *Medical Times*, would be gratefully acknowledged by the whole Profession and, regardless of minor differences, would receive the signatures of every one anxious to have this sickening subject set at rest. It is the only thing left for us to do in the present state of the question for, much as any one might desire to forward the matter by his individual efforts, there are few who have sufficient confidence to put themselves forward by individually petitioning; and it is easy to understand the difficulties which exist, in limited localities, where there are few medical men, and those, unfortunately, too often not agreed amongst themselves, in obtaining signatures to a Petition whose object they are unanimous in wishing to see carried out.

I shall only be too happy to forward my own name to be appended to such a Petition, and I much mistake the feeling of the Profession, if a large proportion of its members are not glad to avail themselves of the like privilege.

I am, Sir, yours very respectfully,
A Zealous Reformer.

UNIVERSITY DEGREES.

[To the Editor of the Medical Times.]

Sir,—I beg to offer the following remarks on the British Universities which have the power to grant the degree of Doctor of Medicine:—

A great movement has taken place in our Profession, within the last five years, and one which, in my opinion, is much calculated to raise the character of the General Practitioner,—I mean the fact of a great number graduating in some University. The members of the Profession who have hitherto done so are those who, from want of the apprenticeship, are unable to go to the Apothecaries' Company for their license, and feel it desirable to possess some medical diploma, or those men who make it the stepping-stone to the license of the College of Physicians, and those who, though possessing the diplomas of both College and Hall, yet still are desirous to obtain the highest honours of their profession,—a less numerous body than the other two, but still, much to my satisfaction, steadily on the increase. Under such circumstances, a few remarks respecting the claims of the various Universities may be useful.

The Universities of Oxford and Cambridge are beyond the reach of the General Practitioner, by reason of the expense, time, and residence required to obtain their degrees. I will, therefore, dismiss them with the remark, that their degrees are most respectable and most honourable. The University of London takes its place next, in consequence of the difficulty of its examination; but this also is beyond the reach of the Practitioner, who has commenced practice since 1840 or 1841, from his being unable to spare time, if in at all extensive practice, to prepare for the numerous examinations from matriculation to the degree of M.D.; but I most highly recommend it to those gentlemen in practice before 1840, or who can spare time to go through the regular routine. Edinburgh comes next, merely because it is metropolitan; but the residence of twelve months which it requires, puts an effectual bar to the practitioner; but in that he has no loss. Its examination is not difficult, therefore its diploma is not held in high repute. As I heard an old practitioner remark, they appear to think that a man must know something of medicine after a residence of twelve months in Edinburgh. I think so too; but they should not take it for granted, and pass so many fools. The same remarks are applicable to Glasgow. I have known men of most inferior attainments, graduates of those two Colleges. Take away the necessity of residence, and continue the present examination, and they will sink below par. I come next to King's College, Aberdeen; though not quite so old as St. Andrew's, yet I take it first, in consequence of the known difficulty of its examination, particularly to students, or men not five years in practice. This University is open to practitioners of five years' standing; its diploma is next in respectability to that of the University of London; and, from what I know of some of its graduates, and the examination they underwent, I look upon it with high respect. I lastly come to St. Andrew's, but, though last, not least; I would prefer being a graduate of it, to either Edinburgh or Glasgow, as far as its examination is concerned. The Professors are all well-known men, and they have sent back many a man who would have passed Edinburgh or Glasgow.* On looking over the *Medical Directory*, I continually see the words Giessen, Erlangen, Heidelberg, &c. What could possibly induce gentlemen,—and some good names, too, amongst them,—to purchase degrees from these Universities? Can they imagine, that the Profession does not know how these diplomas are obtained, or that they can carry any weight with them? Sir, those would-be Doctors are beneath contempt. If men have not the ability to obtain, by fair examination, their diplomas from a British University, let them be content with the ordinary certificates of College and Hall, and not reduce to their own level the possessors of diplomas honourably obtained.

My principal object in writing these remarks is to give an impulse to the present movement. I perfectly agree with a friend, who says, we ought all to be Doctors. The College of Physicians do not like it. No, I should think not. Can I give a greater proof that it is for the benefit of the General Practitioner? The members of that College excel us only in name; let us destroy that superiority.

I am, Sir, with high esteem,
Your obedient Servant,
A Candidate for the Degree of M.D. at London University, and a M.R.C.S.

[We beg to inform our Correspondent that Heidelberg degrees are above price—they cannot be bought.—Ed. *Medical Times.*]

DR. INNIS ON SKIN DISEASES.

[To the Editor of the Medical Times.]

Sir,—I shall feel obliged, if you will allow me to correct an error which appears in the *Medical Times*, of the 23rd inst. I have not read the work of Dr. Innis, "The Skin in Health and Disease," but it appears the Author has, without acknowledgment, abstracted from Dr. Burgess's translation of M. Cazenave's work, a treatment recommended therein, viz., the employment of the vapour of sulphur and iodine in certain affections of the skin, ulcers, &c.

Now, Sir, this plagiarism involves a double petty larceny, for he has attempted to take from me a credit to which I am legitimately entitled, viz., of being the first to employ and demonstrate the high value of these agents in various intractable affections of the skin, ulcers, &c.; and he has also appropriated to himself, from the above-quoted work, the credit to which Dr. Burgess is, I conceive, entitled, for having taken the trouble to inform himself upon, and recommend very strongly, these invaluable remedial agents.

There is this difference, however, between the writers. Dr. Burgess acknowledged, so far back as the year 1842,(a) the source whence he derived his information; whilst Dr. Innis has, in the year 1849, forgotten, or thought it inexpedient, to do so.

A case of obstinate lepra, with long-standing ulcers of both legs, came under my care in November, 1837; another of phagedenic ulceration of the leg, in January, 1838. These were published in the *Lancet*; were subsequently translated and made the subject of editorial remarks in the *Gazette Médicale de Paris*, 1st Juillet, 1838. Drs. P. H. Green, Burgess, E. Johnson, and other medical friends, saw these and other cases whilst under my care. Subsequently, I took occasion to recommend the treatment in various

(a) Vide "Manual of Diseases of the Skin," from the French of MM. Cazenave and Schedel; with Notes and Additions by Thomas H. Burgess, M.D.

affections of the skin, in another publication of mine; and, finally, in 1848, I published a work, of which you did me the honour to speak in high terms in the *Medical Times*, of March last. Under these circumstances, whilst insisting on a priority of claim, which I am prepared to maintain against all comers, it may not be out of place to observe, that subsequent experience and observation, in a pretty extensive field, enables me to assure the Profession that they will, in many otherwise intractable affections, find this remedy a powerful and valuable addition to the too often limited resources of our art.

I am, Sir, your obedient servant,
GEO. ALF. WALKER.

St. James's-place, St. James's-street, June 28.

[The reader will find at page 211 of Dr. Burgess's excellent work a strong recommendation of Mr. A. Walker's remedy.—ED. *Medical Times*.]

THE JOHN HUNTER CLUB.

[To the Editor of the Medical Times.]

SIR,—At last the John Hunter club has spoken. It has chosen a gentleman signing himself "J. H. C." for its mouthpiece, and it strikes me a worse mouthpiece could scarcely have been chosen. A more knock-kneed composition than his epistle I never saw. His awful flounders with "with," "which," "would," and "will;" his tautology, his relatives without antecedents, indicate such a mental condition that one mutters involuntarily, "Alas! the brains are out, and yet the thing won't die." Cunning often fixes on almost brainless pates for her favourite dwelling, so "J. H. C." conceals what the propagandist of the Club let out to "F. R. C. S." Let me seriously entreat the country Fellows to consider the following paragraph:—"That there was an opinion prevalent amongst many of the Fellows, *in which several members of the Council participated*, that as this body was now powerless to select its own members, and as the number of Fellows was on the increase, many of whom *resided in the country, and* THEREFORE had not the means of judging of the qualifications of the candidates, it seemed expedient that some steps should be taken to insure a return of *proper* individuals to the Council, with the view of keeping up its *high* character." So Fellows who reside in the country have not the means of judging of the qualifications of candidates. Alas, poor Fellows! Kiernan, Hodgson, and Dalrymple can only be appreciated by those who still snuff the air of St. Bartholomew's, St. George's, and Guy's. How thankful these country *fellers* ought to be that the London Fellows are kind enough to choose for them. I trust, if any country *Feller* find himself in Lincoln's-inn-fields on the eventful day, he will show how truly the members of the John Hunter Club have estimated his capability of judging for himself, by rejecting Mr. Wormald; but if he should be unwilling to be led by men who, in choosing "J. H. C." for their spokesman, have shown an earnest wish to out-Dogberry Dogberry, for he simply desired to be written down an ass—they have begged to be printed such—he will replace the name of the member of the John Hunter Club by that of one who at least is unconnected with this already too famous institution.

I am, Sir, yours obediently,
AN OBSERVER.

CHLOROFORM IN CHOLERA.

[To the Editor of the Medical Times.]

SIR,—In reply to your Correspondent, who desires to know the mode of administering chloroform by the stomach, I beg to say that it is soluble in brandy, and that this solution will bear to be slightly diluted without precipitation ensuing. This is the best mode of giving chloroform in urgent cases, whether of English or Asiatic cholera. If, however, it is desired to give it without brandy, it may be conbined, as in the following prescription:—

℞. Chloroform, ♏ xx ad. xl; mucil. gummi. acac. ℥iss; syrupi. simp. ℥ss; sp. vini. rect. ʒj; aquæ dist. ad. ℥iij. M.

The chloroform should be dropped into the spirits of wine, and the solution added to the mucilage and syrup, in a bottle. This should be shaken, and the water added by degrees.

A fourth part of the above mixture will be an ordinary dose for an adult.

In these forms, apportioning the dose according to the age, condition, &c., of the patient, we have continued to use it here in cholera, dysentery, and spasmodic affections of the stomach and bowels, with the most satisfactory and remarkable results; and, so convinced am I of its efficacy in cholera, that I do not regard any patient afflicted with this disease as having had a fair chance of recovery in which chloroform had not been used. For further particulars on this subject, I would beg to refer your Correspondent to the cases and accompanying remarks he will find in the *Medical Times* of August the 12th, September 16th, and October the 14th, 1848.

I am, Sir,
Your very obedient servant,
P. BRADY.

Harrow, July 3.

LIFE ASSURANCE OFFICES AND MEDICAL MEN.

[To the Editor of the Medical Times.]

SIR,—The following correspondence has lately taken place between the "Defender" Life Office and myself. As it shows the opinion of the office as to the propriety of paying for what is necessary to their well-doing, you may, perhaps, think fit to make it known to your readers.

Letter (No. 1.) was the usual printed form, requesting answers, &c., to certain queries as to a patient's health, soliciting *an early reply*, which I accordingly gave.

"Crewkerne, May 10th, 1849.

"Sir,—I beg to acknowledge the receipt of a printed form, requiring answers as to the health, &c., of Mrs. E— S— of D—. I am one of those, who think that when questions of this kind, involving great responsibility, are put to a medical man for the benefit of an Insurance Company, that they are the parties to whom the referee should look for payment. On receipt of the usual fee I shall be happy to answer the proposed queries; but, unless I am insured payment, I must, as there will be most probably some trouble in obtaining the desired information from my patient, refuse to fill up the paper. You may, perhaps, be aware, that nearly thirty Companies of the most respectable character have come to the equitable determination of remunerating the medical referee.

"I have, &c., &c.

"John Kelday, Esq., Defender Life Office." "G. F. WILLS.

(No. 2.)

"London, May 11th, 1849.

'Sir,—I am aware that a *few* Companies (not nearly thirty) have recently adopted the practice of paying a fee to the medical attendant of parties proposing to insure their lives; and on behalf of this Company have given the subject great consideration, but have failed to satisfy myself that the demand of such fee has the least connexion with the ordinary principles of equity. I do not mean that the medical attendant should not be remunerated at all, but I do mean that it is not equitable to claim it from the office, while the party proposing Insurance considers himself to be doing thereby a beneficial act both for himself and family. The advantage is not more for the Company than the individual. The individual makes certain statements, which require a certain amount of confirmation before he can attain to the position he desires. His own statements and those of his referees are not those upon which the Company act!! They are, to be sure, made the basis of the contract between the parties, and upon their accuracy and fidelity rest the validity of the contract. It is, therefore, for the interest of the party insured that no false or incorrect statement should be made. I contend, therefore, that it is not inequitable to require him to furnish this evidence at his own expense, in like manner as, when selling property, the vendor not merely asserts his title, but, at his own cost, furnishes an abstract; and, on the other hand, the Company always requires that the proposer shall submit himself to the examination of a medical gentleman on their behalf, and of course they pay such gentleman's fee. I am induced to trouble you with these remarks, only because, by the use of the word equitable in reference to payment of your fee, you seem to imply that a refusal to do so would be inequitable. There are, however, other matters in connexion with this particular case which compel me to require that the fee should be paid by the party proposing.

"I am, &c. &c.,

"G. F. Wills, Esq." "JOHN KELDAY.

"Crewkerne, May 12th, 1849.

"SIR,—In reply to your letter, I beg to state that, unless I am insured remuneration for my report as to the life of Mrs. E— S—, either from the office or from the party proposing to effect the insurance, I cannot make the required return. With respect to your arguments, as to the equity of the fee being paid by the office, I cannot at all agree with you, as the individual whose life is proposed is content to take the state of his health as he gives it himself; but the office, not being satisfied with his statement, requires the certificate of his own medical attendant, who, of course, must be the best judge of his health, and who gives his report for the safety, and, therefore, solely for the benefit of the Company. The Medical Report is often unfavourable, and, therefore, to the disadvantage of his patient. How then can we require, as a general rule, the proposer to pay for what does him no good, and even positive harm, by exposing to other parties, not only the state of his own health, but the general health and predisposition to disease of his family? In the present instance, I have not only not been applied to by the proposer, but do not know his name or his situation in life, and, therefore, unless I am made acquainted with this, or am in some other way insured payment of a fee, which every person must allow to be a just and a well-earned one, I would ask if it is reasonable that I should undertake the responsibility of answering the proposed queries. I still think that the equitable mode of payment is by the Company, even should they think fit to charge the party with a fee after the proposed examination has been passed. You state "that a few Companies (not nearly thirty)" as I mentioned in my letter to you, "have recently adopted the practice of paying a fee." I beg to inform you, however, that my statement is correct, and, on the other side, give you a list of those who published their determination to do so some weeks since, and I believe others have agreed to the plan lately.

"I remain, Sir,
"Your obedient Servant,
"G. F. WILLS.

"John Kelday, Esq., Defender Life Office."

I accordingly gave him a list of twenty-two offices who had determined to pay the medical referee, and I know that there were some others whose names I could not remember.

"Defender Office, May 15.

SIR,—In reply to yours of yesterday I beg to state, that the circumstance of your not having been applied to by the proposer, who has referred me to you; as, also, the fact of your not knowing his name or situation in life, are a strong confirmation of your position in requiring a fee, and I have written to the parties accordingly.

"I remain, Sir, &c., &c.,
"JOHN KELDAY."

Here the correspondence terminated. The proposer came to me, and objected to pay a fee, as he had already paid half a guinea, which he understood to be the fee for the medical referee of the Company, before whom he had been. I gave him a list of some offices which I could recommend, and have not since seen anything of him. I may add, that I do not consider the life to be a very good one; thus affording another proof that it is *solely* for the advantage of the Company that my opinion was asked. I trust that Medical men, by being determined in their opposition to gratuitous opinions to Life Offices, will have the satisfaction of finding, that these will be under the necessity, "however painful," of affording them a just remuneration for a valuable service, saving, perhaps, to them thousands of pounds every year.

I am, Sir, your obedient servant,
G. F. WILLS.

Crewkerne, July 2nd, 1849.

STERILITY.

[To the Editor of the Medical Times.]

SIR,

Reading of late, in the *Medical Times* and its contemporaries, several clever compositions on the cause and cure of sterility in women, it has struck me that the writers thereof can have but one eye, else their dual vision would have led them to perceive that there is another side of the question, viz., the want of fecundity in men, on which side of the subject I confess myself even more curious to be informed, but have never yet been fortunate enough to meet with a case,—whereby I am reminded of the retort in the fable of the Lion and the Painter; and my present writing is to request your kind attention to this sad omission. Yours constantly, "MEM."

MEDICAL NEWS.

Apothecaries' Hall.—Names of gentlemen who passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, 28th June, 1849:—George Gordon Lawrence Williams, Llandovery; Robert Tassell, Wye, near Ashford; Peter Allen, Smarden, near Cranbrook; William Jeynes, St. John's, Newfoundland; Luke Blumer, South Shields.

Royal College of Physicians.—On Saturday last the Harveian Oration was delivered by Dr. Badeley, of Chelmsford, in the presence of a large assembly, after which nearly 100 sat down to a splendid dinner in the large dining-room of the College. The oration, which lasted forty minutes, was much admired for its elegant Latinity, as well as for the liberal sentiments which pervaded it, and was much applauded throughout; being clearly and audibly delivered it was heard by every one present. It comprised the usual commemoration of the benefactors and ornaments of the Profession, and suggested means of increasing the utility of the Institution, and afterwards advocated throwing its doors more open to those physicians whose attainments and skill merit promotion, instead of confining the Fellowship to Graduates of Oxford and Cambridge, as formerly. Amongst the company present were Lord Carlisle, Lord Rosse, P.R.S., Lord Langdale, the Master of the Rolls, the Lord Chief Baron, Barons Alderson and Parke, Mr. Justice Patteson, Mr. Justice Creswell, the Dean of Westminster, Sir H. Halford, M.P., Sir B. Brodie, Sir. C. Clarke, Sir C. Forbes, Mr. Hallam, in addition to Dr. Paris (the President) and most of the eminent members of the Faculty. The grand library, in which the oration was delivered, was elegantly adorned with flowers, and the rostrum embosomed in laurel.

Royal College of Physicians.—The censors elect are Dr. Southey, Nairne, Barker, and Jeaffreson.

Royal College of Surgeons.—The following gentlemen, having undergone the necessary examinations for the diploma, were admitted members of the College, at the meeting of the Court of Examiners on the 29th ultimo, viz., Herbert Brown, Cambridge-street, Hyde-park; Charles Veral, Norton-street, Marylebone; Joseph Bray Gilbertson, Preston, Lancashire; Benjamin Hunt, Ashby-de-la-Zouch; Josiah Robert Jenkins, Ruthin; Henry Day, Norton, Yorkshire; William Edmund Strong, army; William Gregory, Jun., Belle Vue, Finglass-bridge, Dublin; and Charles Alexander Bisset, Peckham, Surrey. At the same meeting of the Court, Mr. Narcissus Collins Hatherly passed his examination for naval surgeon. This gentleman had previously been admitted a member of the College, his diploma bearing date May 2, 1845.

Royal College of Surgeons.—The following gentlemen having undergone the necessary examinations for the diploma, were admitted members of the College at the meeting of the Court of Examiners on the 2nd inst.:—Messrs. Thomas Carey, Midhurst, Sussex; Frederic Charles Spackman, Bradford, Wiltshire; Adam John Cridland, Taunton; William Henry Thornton, Thornhill, near Dewsbury, Yorkshire; John Syer Bristowe, Camberwell; Charles Harper, Plymouth; Alfred Ball, Bishopsgate-street; William Annable Skinner, Headcorn, Kent; Richard Cooper Todd, Dublin John William Billing Steggal, London; and John Buncombe, Taunton.

Appointments.—Professor Owen has just received the diploma conferring on him the distinction of Corresponding Member of the Royal Academy of Sciences of Madrid, and has been unanimously elected an Honorary Fellow of the Royal College of Surgeons of Ireland. These honours indicate the appreciation of the worthy Professor's abilities and talents by the most distinguished home and continental Institutions. It is not a little curious, that these honours should have been conferred on Professor Owen at the moment when his qualifications to a seat in the Council of the Royal College of Surgeons of England have been so freely and inconsistently called in question.—Mr. Charles Henry Hallett, late Demonstrator of Anatomy in the University of Edinburgh, and Student in Human and Comparative Anatomy at the Royal College of Surgeons, has just been appointed Senior Surgeon and Naturalist to the Southern Whale Fishery Company,—an appointment this gentleman has been induced to accept from the excellent opportunities it will afford him of prosecuting a more extended study of natural history and anatomy. Mr. Hallett has been long known to the Profession by some elaborate papers in the pages of our esteemed contemporary, the *Edinburgh Medical and Surgical Journal*, and some that have appeared in this Journal, "On Varieties of the Venous System," of the "Ciliary Ganglion," and "On Fractures of the Hip-joint at an Early Age." We wish Mr. Hallett that success his merits deserve.

Obituary.—On the 1st inst., at Kemerton Rectory, in his 83rd year, Robert Disney Thorp, M.D., father of the Archdeacon of Bristol.

Death of Dr. A. T. Thomson.—It is with great regret that we announce the death of Dr. Anthony Todd Thomson. He died on Tuesday, at his country seat near Ealing. Next week we propose to lay before our readers a short account of the professional career of this very able and much-lamented physician.

London Cutaneous Infirmary.—The Annual Dinner of the London Cutaneous Infirmary took place at the London Tavern, on Thursday, June 14. The Right Hon. Lord Robert Grosvenor, M.P., &c., presided, and amongst the company assembled we observed Samuel Gurney, jun., Esq., Thomson Hankey, Esq., Robert Alexander Gray, Esq., J. H. Goodhart, Esq., Donald Nicoll, Esq., Jonathan Chapman, Esq., David Drakeford, Esq., James Startin, Esq., George Startin, Esq., Standish G. Grady, Esq., Boyes Thornton, Esq., &c. Considerable interest was excited by the presence of Mohammed Bey and other distinguished members of the Egyptian Naval Service. The usual loyal toasts having been severally proposed and duly honoured, the noble Chairman proposed—"Prosperity to the London Cutaneous Infirmary," and dwelt strongly upon the claims the Society possessed on public sympathy and support. He referred to the Hospital of St. Louis in Paris, and expressed his surprise that in a city so celebrated as London for its wealth and benevolent institutions, so little attention should until recently have been paid to that important class of maladies—diseases of the skin. Paris, with only half the population of London, found it necessary to have its Hospital of St. Louis, which annually relieved 30,000 persons, while the metropolis of England, with its 2,000,000 of inhabitants, had, as yet, but this Infirmary, although he hoped that the Committee would succeed in their design of making it the nucleus of an hospital commensurate with the wants of this great city. Various other toasts were proposed and received with much enthusiasm, amongst them, the Noble Chairman, the President, Samuel Gurney, Esq., the Treasurer, J. Gurney Barclay, Esq., the Committee of Management, and Boyes Thornton, Esq., honorary secretary, the Distinguished Foreigners present, &c. From the Report which was read it appeared that the Society was making steady progress in public opinion, although its means are not as yet at all adequate to the demands on its bounty. Since its establishment in 1841 it has relieved upwards of 22,000 persons, the average of which number is daily on the increase, and even a larger number than the above have availed themselves of the excellent suite of baths attached to the Infirmary. In the course of the evening, donations and subscriptions obtained by the stewards were announced to the amount of about 840*l*. There is a further valuable feature in this Institution, particulars of which may be seen on reference to our advertising columns of this day. We allude to the existence of a school for the study of the diseases treated by the Infirmary, the fees arising from which are devoted to the Charity.

Bethlem Hospital.—On Wednesday week the annual dinner in commemoration of the establishment of this Hospital took place in the great hall of Bridewell. Sir Peter Laurie in the Chair. In the speech of the President allusion was made to the new and benign mode of treatment adopted, and which had been attended with the greatest success. The different mechanics had been furnished with tools for carrying on their usual trades, and not one accident had occurred. It had been ascertained that when a patient was in a state of excitement he became calm and reconciled on being led to his place of work, and supplied with instruments which in his hands might be considered most dangerous. Of 320 lunatics in the hospital, 166 had been dismissed apparently cured. The President, in his speech, made the following observation:—"It was the anxious desire of the establishment to get rid of the patients with all possible celerity. The temptation to procrastinate a cure—a temptation so great as regarded a wealthy patient confined in a private establishment, was not afforded in an asylum where there was nothing to pay, and where the most speedy remedies were applied, without regard to the cost or trouble of the application."

The German Hospital at Dalston.—The Annual General Court of the Governors of this Institution was held yesterday at the London Tavern. His Royal Highness the Duke of Cambridge took the chair at twelve o'clock. In his address to the meeting, which was numerously attended, His Royal Highness explained the nature and the purpose of the meeting, viz., the adoption of certain resolutions respecting the manner of the management of the Charity and the election by the Governors of a certain number of members to fill the vacancies occasioned by the outgoing, as provided by the statutes of the Institution, of certain members of the Committee. His Royal Highness congratulated the company on the improved state of the affairs of the Hospital, which had enabled the Committee to acquit all debts which had formerly hampered them, and on the final cessation of those unfortunate dissensions which at one time seriously threatened the existence of the German Hospital.

Health of London during the past week. (From the Report of the Registrar-General.)—The 1,217 deaths registered in the week exhibit an excess of 254 above the weekly average of the quarter, which ends on June the 30th; but this unusual result is due only in part to an increased rate of mortality. The registration of a considerable portion of those deaths on which inquests were held though they occurred at an earlier period, is no completed till the end of the quarter; a fact by which is explained the accumulation of deaths observed in the present return from fractures, hanging, drowning, poison, burns, and some vaguely described as "natural," or "from the visitation of God." The number now returned by coroners, as caused by violence, is upwards of 80, though the weekly average is only 29; those enumerated in the table as "sudden deaths," 46, though the average does not exceed 11; an excess, for the same reason, is found under "apoplexy," the cases returned being 42, while the average is 24. But the mortality from diseases of a tubercular nature, and from those of the organs of circulation, differs little from the average; that from diseases of the respiratory organs falls considerably under it. In the zymotic or epidemic class the increase is remarkable; here, the deaths which in the two previous weeks were respectively 251, 277, were last week 349, whilst the average is 198. The fatal causes in this groupe, which attract notice, are hooping-cough, from which there were 53 deaths, (the average being 36); diarrhoea, from which there were 30, whilst the average is 12; and cholera, from which 124 deaths are enumerated. The recent progress of this disease is shown by the weekly returns; for in four previous weeks the fatal cases were respectively, 9, 22, 42, 49. Last week it was fatal to 76 males and 48 females, of whom only 5 were under 5 years of age, 21 between that age and 15 years, 88 at 15 and under 60, and 10 at 60 and upwards. Few deaths from it occurred in the north districts. Mr. Westerp, the Registrar of St. James, Clerkenwell, reports that a man died from "*fever*" after an illness of six days. He had lain on the floor of a miserable hovel six feet square, and within a few feet of a nuisance which accumulated and overflowed in the court. Two cases are ascribed to intemperance,

two to privation, and a young man of 18 years died in Pancras of "phthisis," while left in a destitute condition by his father, who had deserted him. A woman died in the City-road Sub-district, at the advanced age of 100 years.

THE CHOLERA.—This disease has been on the increase in the Metropolis and some parts of the country during the past week, as we observe with regret that the mortality, in proportion to the number of persons attacked, is as great as ever. It is evident, therefore, that whatever control may be exercised over the premonitory symptoms in the more advanced stages of the disease, no satisfactory mode of treatment has yet been generally adopted. We should be glad to see Dr. Stevens's saline treatment fairly tried, and we trust the members of the Profession will, without delay, direct their especial attention to it, and we shall be most happy to record their experience in the pages of this Journal. In Gloucester cholera has been on the increase, and one of the medical members of the Board of Health has visited the place. He has made a most unfavourable report in reference to the sanitary condition of the city, the sewerage being most defective, and many of the houses in the back lanes in a filthy condition. In Liverpool the returns have been favourable. The French metropolis is almost free from the disease, while in New York and some other large cities of the transatlantic Republic it has been spreading with fearful rapidity.

MR. RENSHAW, the publisher of Dr. Burgess's work on the skin, has applied to the Court of Chancery for an injunction to restrain the publication of a book on the same subject by "J. Innis, M.D," lately reviewed in our pages.

THE LONDON MATERNITY CHARITY.—The Special Committee appointed to examine into the management and constitution of this Society, are, we understand, prepared to recommend very extensive changes, some of them having reference to the medical department.

THE LONDON MUTUAL LIFE AND GUARANTEE SOCIETY.—A new office, starting under the most favourable circumstances, has done itself honour in the recognition of the claims of the Faculty, by a resolution to pay a fee of half-a-guinea in every case when information is given by medical referees, whether the life is accepted or declined. It is to be hoped that all the Mutual Offices will follow this example.

UNITED TWINS.—We have been favoured by Dr. Verhaege, of Ostende, with an account of the female children recently born at Earneghem, in Belgium, who are compactly united together in a similar manner as the Sicilian twins, Ritta and Christina, and the Siamese brothers, whose names we forget. Dr. Verhaege's memoir is accompanied with a drawing, which we will engrave and publish next week.

HALIFAX UNION.—MEDICAL RELIEF TO THE POOR.—A summary of orders, visits, and medicines, supplied to Poor law patients in the Halifax district for the quarters specified below. Halifax district—population, 19,881; area, 990 acres:—

	For the Quarter ending Dec. 25, 1848.	March 24, 1849.	June 23, 1849.
Number of orders for medical attendance from the relieving officer	194	225	176
Visits to the residences of patients	541	510	460
Mixtures dispensed	1,029	1,052	996
Pills	3,157	3,606	3,334
Powders	663	572	481
Lotions	36	46	55
Liniments	45	32	51
Boxes of ointment	36	47	41
Plasters	79	132	126
Remuneration for the duty and the supplies above recorded	£20, or 2s. per case.	£20, or 1s. 9½d. per case.	£20, or 2s. 3½d. per case.

This Table is correct.—FREDERICK S. GARLICK, Medical Officer for the Halifax District.

THE "British Record of Obstetric Medicine, Surgery, and Diseases of Women and Children," edited by Dr. Clay, of Manchester, has ceased to exist. The publication extended to two 8vo. volumes; it was conducted with talent and moderation, and the editor carries into private life the best wishes of the Profession.

MORTALITY TABLE.

For the Week ending Saturday, June 30, 1849.

CAUSES OF DEATH.	Total.	Average of Five Springs.
ALL CAUSES	1217	963
SPECIFIED CAUSES	1214	959
Zymotic (or Epidemic, Endemic, and Contagious) Diseases	349	198
SPORADIC DISEASES:		
Dropsy, Cancer, and other Diseases of uncertain or variable seat	59	48
Tubercular Diseases	190	200
Diseases of the Brain, Spinal Marrow, Nerves, and Senses	145	123
Diseases of the Heart and Blood-vessels	37	34
Diseases of the Lungs, and of the other Organs of Respiration	105	131
Diseases of the Stomach, Liver, and other Organs of Digestion	70	62
Diseases of the Kidneys, &c.	5	11
Childbirth, Diseases of the Uterus, &c.	11	
Rheumatism, Diseases of the Bones, Joints, &c.	11	
Diseases of the Skin, Cellular Tissue, &c.	3	1
Malformations	1	3
Premature Birth and Debility	36	21
Atrophy	16	17
Age	37	50
Sudden	16	11
Violence, Privation, Cold, and Intemperance	93	33
Causes not Specified	3	4

TO CORRESPONDENTS.

We are obliged to Mr. M'Bean for his communication, which, however, we must decline publishing. We do not think that the gentleman in whose praise, the letter is written would be well pleased to see it published, however well intentioned it may be.

"'Tis pleasant, sure, to see one's name in print,
A book's a book, although there's *nothing* in 't,"

may be, and is, very true in some cases; but we are quite sure it does not apply to the gentleman in question.

We have received a letter from "A King's College Hospital Student," upon the subject of Morbus Coxarius. We never publish such letters anonymously. If the writer has any charge to make, let him make it openly, and not under the protection of a *nom de guerre*. If he requires information, we are sure he has only to apply in the proper quarter; and, meanwhile, we ourselves refer him to a communication by Mr. H. Smith, published on the 12th of March, 1848.

"Mr. Gwydir" is informed, that Dr. Stevens will shortly publish "instructions for the treatment of the cholera." We are quite sure, however, that he will readily communicate with Mr Gwydir on the subject; meanwhile, in reply to the many queries we have received upon the subject of the saline treatment of cholera, we have only to refer to Dr. Turley's letter in this Journal, at page 594, in which Dr. Stevens' mode of treatment is detailed.

"Medical Provident Institution."—We have read Mr. Hawtayne's letter and papers with much pleasure. We shall, probably, allude to the subject next week.

"Junior."—Hydrocyanic acid, as a remedy for blindness, has not been found by experience to effect those cures which its advocates at one period asserted that it would. The circumstance, that the eyes of those who had destroyed themselves by prussic acid remained clear and dilated, led to the employment of this agent for relieving many of the diseases to which the organ is subject. Many experiments were said to have been performed with surprising success; and it was even stated that blind persons were returned to sight. The mode of application is, by putting the fluid in a small bottle, with a mouth shaped to cross the hollow of the eye. With the acid is put a little asbestos, to act as an absorbent, and the vapour merely comes in contact with the diseased eye. The cases said to be most benefited by the acid are, opacity of the cornea, rheumatic ophthalmia, staphyloma, amaurosis, and cataract. We have employed it in some cases with apparent success, in others without any marked benefit.

"L. S. G., Holloway."—1. Swammerdam was aware of the fact of the contraction of the muscular fibre when acted on by the influence of two metals, copper and silver; he performed the experiment before the Grand Duke of Tuscany, nearly a century before Galvani announced his discoveries. 2. In the higher animals, the electric currents are but feebly developed.

"Nestor."—The earliest notice of the plant is about the middle of the 16th century. The alkaloid contains a large amount of nitrogen.

"Chemicus."—Olefiant gas, when condensed, appears as a beautifully transparent, colourless liquid; it is not solidified, and will dissolve oily, resinous, and bituminous bodies.

"M. B., Cheltenham."—It belongs to the class annelides.

"An old Subscriber."—The Charter has not lately been altered. Licentiates who have not graduated at Oxford or Cambridge are now eligible for the Fellowship.

"An Irish Medical Student."—The University never adopted such a practice.

"Amicus."—Craw-craws is generally found amongst the negroes shipped from the coast of Africa, but is frequently communicated to the crew of the vessel. The disease is found principally on the outer parts of the arms, from the wrists up to the elbows, and will spread over the whole body if neglected. It resembles scabies, but is more annoying. The internal and external use of sulphur, with a generous diet, are the means employed for its cure.

"Delta,"—should consult Aiken's Biographical Memoirs of Medicine in Great Britain.

"A Pupil" can, with the consent of his master, spend a portion of his time in attending lectures, &c., without endangering his indentures. The Apothecaries' Company would not offer any objections.

"Medicus."—The Indian hemp was employed by M. Willemin, in Egypt, under the form of resinous extract, as a "cure" for cholera, and, it is said, with marked success. We have not heard that it has been used with the same beneficial results in this country.

"Æsculapius."—Hoblyn's Dictionary of Medical Terms.

"A Member of the College."—It is a matter in which we cannot interfere.

"Justitia."—A person having only a foreign diploma cannot recover for medicine and attendance.

"Half-pay."—Yes; and the fever is sometimes generated by a foul state of the hold of a vessel.

"A Correspondent" informs us, that he has treated three cases of facial neuralgia with creosote with entire success. He administered the remedy in the dose of one drop every four hours. After the first two doses, the paroxysms were relieved; and the third entirely removed the disease, which did not return.

"M.D. and a Subscriber."—It is possible for a child to be born alive after the death of its mother. Dr. Taylor relates a case in which a woman having expired during labour, the accoucheur, on his arrival, immediately introduced his hand into the uterus, ruptured the membranes, and extracted a male infant, apparently dead. It was, however, speedily resuscitated by the ordinary means.

"J. B., Lincoln."—The Faculty of Medicine confers two degrees, viz., Doctor in Medicine and Doctor in Surgery. The education of the candidates for either of these diplomas is the same.

"Medico-Chirurgus."—Creasote is prepared by rectifying tar by successive distillations, till the oil which passes over becomes heavier than water. This is digested with a solution of caustic potash, which dissolves the creasote. When the liquor is exposed to the air, it becomes brown, and being then neutralized by an acid, the creasote separates. This process of solution in an alkaline liquor, and precipitation by an acid is to be repeated until the solution is no longer browned by exposure to air; the creasote is then pure.

"Adolescens."—The Iatro-mathematicians were a medical sect who endeavoured to explain the actions of the living body, and the operation of remedies, on mechanical principles. The atomic philosophy of Descartes revived the sect in modern times, but it is of high antiquity.

"A General Practitioner."—The Chancellor makes the regulations and appoints the fees.

"Mr. Evans."—We cannot suggest a remedy.

"A Student of University College."—The student's number of the "Medical Times" will give all the information which our correspondent needs.

"A Retired Practitioner."—There is no prospect, whatever, of a Medical Bill being introduced into Parliament this session.

"A Junior Surgeon."—All ships carrying a hundred or more passengers, must have duly-qualified surgeons, and a proper supply of medicines. The salaries of the medical officers we cannot state.

"Trinity College, Dublin."—Yes; and a petition must be sent to the magistrates, at the Quarter Sessions.

"James."—Acupuncture is easily performed by running in five or six needles with a rotatory motion.

"Chirurgus."—The affection is malignant, and the only remedy is extirpation with the knife.

"Inquirer."—The coroner had no right to call in question the qualification; and the fee can be recovered in the County Court.

A Correspondent, with the signature of "R.," writes:
"I beg leave to correct a statement of Dr. Massie's, in your publication of Saturday last. He ascribes the use of nitric acid in the cure of piles to Dr. Cusack. In so doing,—I am sure quite unintentional on his part,—he has given credit where it is not due. It was the late Dr. Houstun who first introduced the use of the remedy."

ORIGINAL LECTURES.

LECTURES
ON THE
PROCESSES OF REPAIR AND REPRODUCTION AFTER INJURIES.
DELIVERED AT THE
ROYAL COLLEGE OF SURGEONS OF ENGLAND.

By JAMES PAGET, F.R.C.S.
Professor of Anatomy and Surgery to the College.
[Reported for the "Medical Times."]

LECTURE III.

Healing by immediate union; its relation to Hunter's "Union by the first Intention." Description of cases. Essential characters of the process, the conditions necessary for it.—Healing by primary adhesion; its similarity to Hunter's "Union by the adhesive inflammation." General account of the process, and of its relation to other modes of healing.—Healing by granulations. General stages of the process. Periods of repose and of increased vascularity. Production of new substance. Formation of granulation-cells, and their development into cellular or connective tissue and cuticle, their deviations from this process.

MR. PRESIDENT AND GENTLEMEN,—In the last lecture I directed your attention to the distinction which Hunter drew between external and internal injuries, and the processes of healing in each. But it is necessary not to draw too close a line between these several processes, because that which determines the production of these materials seems to be the amount of violence which has been done to the parts; this one traces constantly after division of tendons; after the second or third day, the effusion of the more proper repairing matter begins, and takes its way through nucleated blastema; and I will now only add this—that the process of inflammation appears to be essential only to the production of the material; if it continues, it hinders all the subsequent stages of the development. I come now to speak of the healing of wounds by immediate union. This, as I before observed, is almost identical with what Hunter calls "union by first intention;" it is accompanied by effusion of blood, which becomes organised into new tissue; and I showed that Hunter was only just right in supposing that blood only forms the bond of union; but that he was quite right in believing that it was accomplished by union without any process of inflammation. I have adopted the term "immediate union" from Dr. Macartney, who says:—

"The circumstances under which immediate union is effected, are the cases of incised wounds that admit of being, with safety and propriety, closely and immediately bound up. The blood, if any be shed on the surfaces of the wound, is thus pressed out, and the divided blood-vessels and nerves are brought into perfect contact, and union may take place in a few hours; and as no intermediate substance exists in a wound so healed, no mark of cicatrix remains behind. We have familiar examples of this mode of healing in slight cuts received on the fingers, which, after being bound up, if no inflammation be induced, perfectly heal without the individual having any unpleasant sensation in the part after the moment of the infliction of the wound. A case has been lately communicated to me, of a considerable cut of the hand having been cured by this mode of direct union, without any sensation of pain, and in the short space of four or five hours."

Now, it is singular that he should have limited the instances of immediate union to such trivial ones as these, for many larger wounds, in favourable circumstances, are thus healed. Those examples are the best in which flaps of skin are raised up and then pushed along to replace some other wounded surface. The instances in which I have best observed it have been after operations for the removal of the mammary gland. (Diagram).—Here, after the removal of some skin, the rest of the surface is exposed by reflecting from it an upper and lower flap; the gland is then removed, and these flaps are laid down on the exposed surface of the fascia. In these cases there is a process of immediate union without the production of lymph to form it. The following case will illustrate the process of healing:—A female, aged 33 or 34; a gland was removed, and directly afterwards the flaps were laid down, and fastened with isinglass plaster. They appeared to unite in the ordinary way, and there remained only a narrow space between their edges, in which space granulations arose from the pectoral muscle. Three weeks after the operation these were making good progress towards cicatrization; but erysipelas and phlebitis ensued, and the patient died in four or five days. I expected to find the evidences of union by organised lymph, or, possibly, blood. But neither existed; and the state of parts cannot be better described than by saying, that scarcely the least indication remains of either the place where the flap of skin was laid on the fascia, or of the means by which these parts were united. It was not possible to distinguish the relation which these parts held to each other from that which naturally exists between subcutaneous fat and the fascia beneath it. There was no unnatural adhesion; but, as the specimens will still show, the subcutaneous fat which did lie over the mammary gland is now connected with the fascia over the pectoral muscle, just as (for example) the corresponding fat below the clavicle is naturally connected to the portion of the same fascia that lies there. I could find small points of induration where, I suspect, ligatures had been tied, or where possibly some slight inflammation had been otherwise excited; and one small abscess existed under the lower flap. But with most careful microscopic examination, I could discover no lymph, only small quantities of what looked like the débris of such oil-particles or corpuscles of blood as might have been between the surfaces when the flaps were laid down. The opportunities of examining wounds thus healed being uncommon I thought would justify an experiment; I therefore reflected a portion of the skin from the back of a rabbit, which was then replaced and fastened with sutures. Three days afterwards the rabbit was killed; where the edges of the skin had been retracted from each other, and about half an inch under the edge of the replaced flap, there was manifest adhesion with effusion of lymph; but through all the rest of the space, it was not possible to determine where the skin had been raised. It might have been suggested, that the lymph had again absorbed; but in this case, within three days would have been quite enough to determine whether there had been any lymph. During life, the same process may be watched. In four or five days after the removal of a breast, the flaps do not move at all stiffly, but will adopt that easy sliding which is peculiar to connexion of the skin with the subjacent fascia. Such is the process of healing by immediate union, and which really admits of no very long description. It is, of course, by far the best mode in which any wound can be healed, and two conditions seem to be necessary to it,—1. Exact coaptation of the parts which are separated; and, 2. The absence of all those circumstances which produce inflammation. The old plan of treatment is not so generally employed as it might be in the removal of subcutaneous tumors, where, generally, the flaps of skin are merely laid down. I believe that, in those cases, if the older plan, such as softly padding all the parts about the wound, were adopted, it would be better; while the danger of exciting inflammation is not so great, if it be remembered that the union will be accomplished in about two days, or not at all. Now, suppuration does not occur within two days, and hence there is no danger from this source. If the union is not effected in this period, we may be sure that it is a mode of healing in which there is no hope.

The second mode of repair which I enumerated is that of primary adhesion, and is that which Mr. Hunter called "union by adhesion," or "union by the adhesive inflammation." He says: "Where the former bond of union is lost in a part to produce a new one, a second operation takes place, namely, inflammation. If the divided parts are allowed to remain till the mouths of the divided vessels are entirely shut, inflammation will inevitably follow, and will furnish the same materials for union which are contained in extravasated blood, by throwing out coagulated lymph; so that union may still take place, though some time later after the division of the parts. This inflammation I have called the adhesive." Mr. Palmer, in commenting on this passage, says—"It is now generally considered that union by the first intention and adhesive inflammation are essentially the same processes, modified by the degree of inflammation. Union by the first intention is uniformly attended with some degree of pain and swelling, together with increased heat and vascularity, which, taken conjointly, constitute the definition of inflammation." And then: "According to the modern views, the modes of union above detailed are always accompanied by adhesive inflammation. The parts are united, not by the extravasated blood becoming vascular, but by the effusion and organisation of coagulable lymph." After what I have said of immediate union, it may appear that Hunter was more right in his views than his successors, and it is curious to observe how this theory has come to be thrown away. It seems to have been thus: Evidence was found leading to doubt as to blood becoming a bond of union; then as it was held that there must be some intermediate bond, none was known but coagulable lymph, and so it was supposed that blood was necessary to the healing of all wounds. The best examples of union by primary adhesion are those of incision through the skin. Here, when the cut surfaces are not in exact contact, the wound is exposed, and lymph is formed and fills up the space; or, when they are in contact, the sutures, or other means employed to keep them so, excite inflammation enough for the production of some lymph between them. The lymph organising itself, and becoming vascular, connects the two edges or surfaces, and forms between them a thin layer of cellular tissue, on the surface of which, if it be exposed, a very delicate layer of cuticle is developed. Such a wound is rarely healed without a scar. The lymph effused in the healing by primary adhesion always, so far as I know, developes itself through nucleated cells, as the lymph of acute inflammation does; doubtless the whole process is very similar to that of the adhesion of inflamed serous membranes. It may take place very quickly. It did so in one case, in a wound made seventeen hours previously. If a common abscess be opened, and the edges of the opening are not very thin, they may be found united, except at the central part, in eighteen or twenty-four hours, with a delicate pinkish substance, which is the new lymph; and in this time it is probable that the new lymph has acquired blood-vessels. But the earliest production of vessels with which I am acquainted was in forty eight hours, in a boy who lived eighty hours after a lacerated wound had been made through the abdominal walls, and in forty-eight hours of the eighty, he was so clearly dying, that no reparative process could have been going on. After death I examined some of the new material. A portion of the edges of the wound was united with lymph, which presented cells, like granulation cells, and the blood-vessels were existing loose. But I cannot complete the history of this union by primary adhesion, without mentioning the manner of parts healing by granulations and by secondary adhesion. With regard to a comparison of these two modes, every advantage is in favour of immediate union, for primary adhesion has not only the fault of being a slower process, but the inflaming material is apt to pass into a process of suppuration, and may become morbid. The instances in which the process of union by primary adhesion is shown, are those of operations for hair-lip, in which a very narrow cicatrix may be found existing, but a cicatrix still, and this in all cases marking the existence of a new tissue, and never acquiring the character of a perfect lip. But passing to the consideration of healing by granulations, and by secondary adhesion. Instances of these modes are found, after amputation of the limbs, where the surfaces of the wound are not united by either of the means already described, but are left to granulate; or such cases as the removal of a breast, and subsequent suppuration of the flaps and the exposed fascia; or such as wounds into inflamed parts, when the edges

gape wide asunder, and the spaces left between them are filled up with granulations. Granulations will generally arise on all wounded surfaces that are left open to the air and are not allowed to dry; they will do so whether this exposure be continued from the first infliction of the wound, or commence after the edges, which have been brought together, have been again forced asunder by the swelling of the deeper seated parts, or by hæmorrhage, or secretion of fluid, between them. Exposure of a wound to the air is not prevented by any ordinary dressings; the air that is enclosed beneath them, or that can penetrate them, appears to be quite enough to determine all the difference of the events that follow open and subcutaneous injuries. The simplest case for illustration is that of an open gaping wound, which, from the time of its infliction, is only covered, as in ordinary practice, with water dressing, or some soft and moist substance. Blood gradually ceasing to flow from the surface of such a wound, one may see still some blood-tinged serous-looking fluid, oozing from it; and the material on the surface of the wound, examined with the microscope, will be found to contain an abundance of the white corpuscles of the blood, imbedded, apparently, in a fibrinous film. The existence of these corpuscles on the surface of the wound, especially on those of wounded muscles and fasciæ, appears to depend only on their peculiar adhesiveness. One sees them adhering much more firmly than ever the red corpuscles do to the walls of the capillary blood-vessels, and to the glass on which they are examined; and I should think we may thus explain their collecting on cut surfaces; while the other constituents of the blood flow away, the white corpuscles, and probably also some of the fibrine, quickly coagulating, adhere to the surface, which, in comparison with what they naturally flow over, is very rough, and therefore favourable to the quick coagulation and entangling of the fibrine.

I am not aware what share the white corpuscles take in the healing of a wound, no observations having been made to prove this. They certainly do not hinder it: for it is by many believed to be favourable to union by adhesion, to leave cut surfaces exposed till they appeared glazed over with a whitish film, and then to put them into contact. This glazing consists of fibrine and white blood corpuscles. It is probable the corpuscles are organised. If a wound be still left open, this glazing remains on such parts as it may have formed on, especially on the exposed muscles. No evident change ensues in it, except that it appears to increase slowly, and makes the surface of the wound look as if covered with a thin greyish layer of buffy coat. This increase of glazing is the prelude of the formation of granulations; but while it is going on there is, in and about the wound, an appearance of complete inaction,- a sort of calm, in which scarcely anything appears except a slight oozing of serous fluid from the wound. The calm continues from one day to eight, ten, or more, according to the nature and extent of the wounded part, and the general condition of the body. In a cut or sawn hard bone, ten days at least will elapse before any change is manifest; in cancellous bone the change ensues a few days more speedily; on the under surface of a large flap of skin, with subcutaneous fat, three days may thus pass without change; on the cut or excoriated surface of the more vascular part of the skin, two days or three. These periods of repose after severe injury are of equal interest in physiology and in surgery; but in the former it is only the interest of mystery. Observations, made by Mr. Travers, on injuries of the webs of frogs, make it probable that the blood is stagnant for some little distance from the wound during several days after the injury: but why it is so, and what are the changes ensuing in and about it, preparatory to its again moving on, we cannot tell. There is, however, coagulation of blood in the vicinity of the wound, then a certain quantity of glazing matter, and then there occurs an increased supply of blood to the place where it was stagnant. This may be observed well in the case of bones, of which a very good one existed in St. Bartholomew's Hospital, where there was exposure of the vault of the skull; for many days the bone was unchanged, and it was supposed that it would proceed to exfoliation; but after some days a few rosy points appeared on its surface, and these multiplied and enlarged, and from each of them granulations grew up till the whole surface of the skull was covered. We watched them nearly every day, and it was evident that, in all cases, an increased supply of blood preceded the production of the new material from which granulations were to be formed. Doubtless just the same happens in soft parts as in bone; so that it may be stated generally that the first visible change that ensues after the period of calm, is an increased supply of blood to the parts in which repair is to ensue. This, probably, corresponds exactly with the increased afflux of blood which ensues in inflammation. The process of granulating displays herein two points of resemblance to inflammation, and of dissimilarity from natural processes; namely, 1st, that the increased quantity of blood moves more slowly than in health, while, in the naturally increased supply, its movement is not retarded; and, secondly, that the increased supply precedes the increased production of material.

The effusion of the material that is to be organised into granulations next follows. No account of this process of effusion, so far as it is visible to the naked eye, can be better than Mr. Hunter's; he says: "I have often been able to trace the growth and vascularity of this new substance. I have seen upon a sore a little white substance, exactly similar, in every visible respect, to coagulating lymph. I have not attempted to wipe it off, and the next day of dressing I have found this very substance vascular; for by wiping or touching it with a probe it has bled freely. I have observed the same appearance on a bone that was laid bare. I once scraped off some of the external surface of a bone of the foot, to see if the surface would granulate. I remarked, the following day, that the surface of the bone was covered with a whitish substance, having a tinge of blue; when I passed my probe into it I did not feel the bone bare, but only its resistance. I conceived this substance to be coagulating lymph, thrown out by inflammation, and that it would be forced off when suppuration came on; but, on the succeeding day, I found it vascular, and appearing like healthy granulations." Such is the process one may trace every day, and to this description little can be added more than the microscope has shown. In the minute structure of granulations, or, at least, of such growths of new substance as present all the characters that we imply by that term, —the bright ruddy texture, the pointed and granulated free surface, the succulency and abundant supply of blood,—in these, we may discern two varieties, corresponding with the varieties of lymph that I have already spoken of. For, in subcutaneous injuries or diseases, granulations sometimes form which develope themselves into cellular tissue, through nucleated blastema; so I found in a case of simple fracture, in which the ends of the bone remained long ununited; they were enclosed in a cavity formed by condensation of the surrounding tissues, but containing no pus, and, in eleven weeks, were covered with a distinct layer of fluid granulations. But in by far the greater proportion of cases, granulations are only formed in exposed injuries; in these they consist of cells, that may develope themselves into fibro cellular tissue. Cells upon cells are heaped up together in a layer, from half a line to a line thick, without apparent order, and connected by very little intermediate substance. Singly, they are colourless; but in clusters, they are ruddy, even independent of the bloodvessels. In granulations that are making healthy progress, one can especially trace that multiplication of nuclei of which I have already spoken. In the same, too, one can conveniently trace the cells in various stages, according to the position they occupy: the deeper-seated ones being always most advanced, and often much elongated or nearly filamentous; while the superficial ones are still in a rudimental state, or near the edges of the granulating surface are acquiring the character of epithelium-cells. The cellular tissue thus constructed by the development of the granulation-cells finally assumes all the characters of the natural examples of that tissue. Thus it is found in the layer of substance of which scars that are formed in the place of granulating wounds are composed. After some time, also, elastic tissue is mingled with the fibro-cellular; but this, as I have already said, appears to be effected by a later process. I found in one case no elastic tissue in scars that had existed, the one twelve months, the other eighteen months; but in scars several years old I have always found it. The cuticle, also, that forms on granulations gradually approximates more nearly to the perfect characters, and, like the fibro-cellular tissue that it covers, presents the interesting fact of adaptation to the purposes of the part on which it is placed. Thus, in granulating wounds, or ulcers on the sole of the foot, one may often see that, from the first, the new cuticle is more opaque and thicker than it is on other parts, on which the natural cuticle, in adaptation to the protection required from it, is naturally thinner; and let it be observed, that this peculiar formation of the new cuticle is in adaptation to conditions not yet entered upon. It surprised Albinus when he saw in the fœtus, even long before birth, the cuticle of the heel and palm thicker than those of other parts,—adapted and designed to that greater friction and pressure to which, in future time, they would be exposed. It is the same when, in adult life, new cuticle is to be formed on the same parts; while it is forming, all pressure and all friction are kept away, yet it is constructed in adaptation to its future exposure to them. Surely, such a provision is, beyond all refutation, an evidence of design; and in this fact we may discern another instance of the identity of the powers that are put in operation in the acts of first construction and of repair.

LECTURES
ON
THE CHEMISTRY OF THE POISONS;
OR, ON
PRACTICAL TOXICOLOGY.
SHOWING THE APPLICATIONS OF CHEMISTRY TO THE DISCOVERY OF CRIME.

By H. LETHEBY, M.B., Lond:
Lecturer on Chemistry at the Medical College of the London Hospital.

LECTURE II.

A further consideration of the circumstances which tend to increase the crime of secret poisoning.—As 2ndly, A want of watchfulness on the part of medical men; cases of imperfect registration; necessity for *post mortem* examinations.—3rdly, Negligence of county coroners; usual character of a "crowner's quest;" unsatisfactory results thereof; indefinite form of their verdicts, remarks thereon by Mr. Farr and the Registrar-General.—4thly, False parsimony of the county magistrates; comments thereon by Sir James Graham.—5thly, Indisposition of judges and juries to convict; illustrative cases.

At the conclusion of the last lecture, gentlemen, I was alluding to the circumstances which tend, in my opinion, to promote the crime of secret poisoning. And I mentioned, that the chief and most common of these was, an unrestricted trade in poisons, whereby any individual is enabled to purchase and use the most deadly drugs, without let or hindrance.

A second circumstance, which, without doubt, tends to give encouragement to this crime is, *a want of watchfulness on the part of medical practitioners;* for I fear that some of the members of our Profession are too apt, either from carelessness, ignorance, or an indisposition to be engaged in a criminal prosecution to slur over the symptoms which are manifested in doubtful cases, and to impute them to the operation of some common or indefinite cause. I must refer you to the Annual Reports of the Registrar-General for evidence on this point, where you may obtain ample proof, not only of the correctness of the statement just put forth, but also of the truth of an observation which I made during the last lecture, namely, that by far the greater number of deaths from poison are attributed to other than right causes, and are thus rendered exempt from all public inquiry. Let me give you a few instances of this.

In the Fifth Annual Report, issued by Mr.

Graham, it is stated, that 343,847 deaths occurred in England during the year 1841. And, of these, 24,563 are set down to *convulsions*; 53, to *spasms*; 20, to *cramp*; 9, to *spasm of the lung*; 14, to *spasm of the heart*; 55, to *cramp in the stomach*; 16, to *syncope*; 58, to *dyspepsia*: 3, to *gastrodynia*; 2, to *bile on the stomach*; 2, to *overflowing of bile*; 4, to *vomiting*; 10, to *surfeit*: 2, to *flatulence*; 2, to *polypus of the heart*. In all, 24,799 cases, in which the causes of death were evidently not ascertained, but were passed over by the medical attendant, and registered in a manner which the vulgar alone could consider as satisfactory. And, if to this number, I were to add the 6980 cases of *gastritis*; the 3240 of *diarrhœa*; the 515 of *dysentery*; the 443 of *cholera*; the 847 of *colic*; the 3961 of *sudden death*; and the 7183, in which the causes of death are *not specified*, I dread to think what might be the total amount of murder, and criminal conduct which, in that one year, was cloaked over by the negligence of our professional brethren.

Now, it rests with you, gentlemen, to improve this condition of things; and you can do so by noting carefully, methodically, and attentively, every circumstance which is connected with the history of doubtful cases; remembering, that when such cases terminate fatally, it is your duty to insist on having *post mortem* examinations; and, in fact, I may say that it is your duty, in all cases, to satisfy yourselves most thoroughly as to the cause of death, before you venture to record it upon the register. Herein, let me tell you, is your strength; and you may always use it without any compromise of dignity or reputation. It is a power, moreover, which will, at all times, enable you to disclose the practices of the secret murderer, and thus to do more for the protection of society than even the law itself has the means of accomplishing.

And, gentlemen, if, after you have proceeded with an investigation in this careful manner, it should fall to your lot to discover crime, and to appear in a court of justice as a witness in the case, depend upon it you will receive the highest compliments from the judge, who will not fail to allude to the conduct of the medical witness, whose watchfulness had obviously been the means of bringing an atrocious criminal to the bar of justice, and whose evidence had, perhaps, been sufficient to convict him.

A third cause, which operates in promoting the intentions of the secret poisoner, *is the gross negligence manifested by many of our county coroners.* Some of you will full soon have an opportunity of witnessing the farcical proceedings which are set on foot by these worthies, and of knowing, that a "*Crowner's Quest*" is, as Dr. Smith says, conducted in very much the same style as are the affairs of a country club, saving, that in the latter case, the business is, possibly discussed with more patience, and the truth is more frequently elicited. Too often are important grounds for inquiry slurred over; and evidence is frequently taken in such a way as manifestly shows that it is not wanted, any further than may be necessary to make a sufficient show on the face of the proceedings. This being accomplished, if no troublesome person be present to disturb the even tenour of the way, and no unlucky juryman of sufficient intelligence to confuse the affair by putting an awkward question, the Coroner tells the jury what they are to do; the jury do as they are bid, and everybody gets away in good time for dinner, or for supper as the case may be.

The inefficiency of these Courts has at length become so notorious, that the attention both of the public and the Legislature has been called to it; for how many cases have lately happened in which poison has been detected in bodies, months or even years after they had been buried, and even after they had been exposed to all the formalities of a coroner's inquest, and their deaths recorded as being due to the "Visitation of God." Look at the series of Shapwick murders, the perpetrators of which were tried in the West of England in 1844; and to the recent "*Burial-Club*" murders of Lancashire, Cambridgeshire, Essex, and Norfolk, and let *them* testify as to the negligence of our country coroners. Well, indeed, has Mr. Farr remarked, "that the ordinary mode of conducting inquests is not calculated to inspire either the criminal with dread, or the public with safety."

If you turn to the Fourth Annual Report of the Registrar General you may see that out of 33,881 inquests which were held in the years 1838 and 1839, there were 6708 in which the causes of death were not determined, notwithstanding that in every one of these cases the inquiry was instituted for the express purpose of ascertaining this point. And in the Report for the year 1841, Mr. Farr states, that in two out of every three cases of sudden deaths in which inquests were held, no *post mortem* examinations were made, and the causes of death were, therefore, not specified. A negligence of so gross and wanton a character could hardly be expected to be carried on without some comment being made thereon by the Registrar-General; and hence, in the year 1845, he forwarded a letter to every coroner in England, urging him to be more careful in the conduct of his inquests, reminding him of the intention of his inquiries, and requesting him to improve upon such verdicts as "*died by the visitation of God*," "*found dead*," or "*drowned*," "*died by accident*," "*died from grief*," "*from passion*," "*from anxiety*," or "*from a broken heart*." He informed them, moreover, of a circumstance which concerns you,—one which is alluded to by all authorities in medical jurisprudence, and which is clearly sanctioned by the Government, viz., that the causes of sudden death, often involved in great obscurity, can only be ascertained by an inspection of the principal organs of the dead body; and he further endeavoured to put coroners on the alert by saying, that the crime of poisoning had increased during the last century, and that this was doubtless owing to the number of deadly poisons which were so accessible in every chemist's shop.

It does not appear, however, that these things have undergone any material improvement. Indeed, a consideration of the duties of a coroner, and of the mode in which inquests are generally conducted, together with the fact that hardly any important alteration has taken place in the law which relates to such inquiries since the time of Edward I.,—that is, for a space of nearly 600 years, must naturally excite in us a considerable amount of astonishment. It is, moreover, a source of much concern to us to know, that while the legislature has been busying itself in matters which relate to all the common affairs of life, it has bestowed no attention whatever either upon this or upon many other sanitary subjects, which are admitted, on all sides, to have an important influence on the life and well-being of the community.

A fourth circumstance, which has a tendency to encourage the practices to which I am alluding, is *the false parsimony of the county magistrates*—a parsimony which leads them too often into the wanton commission of the very gravest errors. I have, for example, known that some of these gentlemen, who are ever watchful for what they term the pecuniary interests of their respective districts, have slurred over the facts of a criminal case, and have put an end to all further proceeding in it, for fear of entailing on the crown, the county, or the parish the expenses of a legal prosecution.

Nor do the authorities to which I am referring merely cripple the powers of justice in so far as relates to their own jurisdiction, but they must need do more; for, having some control over the expenses which are incurred by coroners, they will frequently refuse to sanction the payment of money which either has, or ought to have, been spent by these officers in the proper performance of their duties. In the year 1846 this matter was referred to in the House of Commons; and Sir James Graham, in commenting on the cases of poisoning which had recently occurred in Norfolk, said, that there was reason to believe that no fewer than twenty persons had died from poison administered by one individual, and in none of these cases had inquests been held. This, he remarked, had arisen from an indisposition on the part of magistrates to pay the expenses which are connected with coroner's inquests; and he stated that the magistrates of Devon had even gone the length of refusing to pay the costs of any inquests where the verdict was "Died by the visitation of God." Here, therefore, although the matter was publicly discussed, and even severely commented on by the Home Secretary, yet no effort has been made either to remove the evil, or to protect society from the recurrence of a similar enormity.

5thly. *I must refer to the indisposition which exists on the part both of judges and juries to convict, as another circumstance which tends, in my opinion, to give encouragement to the crime of poisoning.* And I hardly know how I ought to express myself upon this notorious and important fact. Perhaps the best mode of treating the subject would be merely to refer to a case or two by way illustration.

Case 1. At the trial of Ann Mather at Liverpool, in December last, for the murder of her husband, it was proved that the prisoner had purchased arsenic; that she had, on the same day, made a pudding for her husband; that he partook of this pudding, and suffered immediately afterwards from effects which are precisely similar to those occasioned by arsenic. It was further proved by means of a chemical examination of the dead body that arsenic existed therein. Nevertheless, the counsel for the prisoner, after speaking for three hours on the subject, was enabled to convince the jury that *the evidence only went to show that the prisoner had purchased arsenic, and that the deceased had died from the effects of arsenic*; "but," continued he, "there is a gap between the proof of these facts, and that of the wilful administration of the arsenic by the prisoner, which cannot be overleaped." And so the jury believed, for the prisoner was acquitted.

Case 2 is of a very similar character. In the month of August, 1847, a woman, Mary Lennox, was charged with the murder of her husband by poison. It was shown that the deceased was at work and well up to the dinner-time of a certain day; that his wife had prepared the dinner which he took on that day; and that immediately after he had partaken of this meal he became sick, and in a short time died with all the symptoms of poisoning by arsenic. Dr. Glover analysed the tissues of the body, and found arsenic therein. It was further proved that his wife had purchased arsenic, for the purpose of poisoning rats, on the very morning of the day on which deceased was taken ill. But, for all this, it was argued by the advocate for the prisoner—first, that it was highly probable that Dr. Glover was mistaken, and that arsenic did not exist in the body; and secondly, that even if it should be admitted that arsenic was present therein, the admission did not prove that the woman had given the poison to deceased, but it merely went to establish the fact of a strange coincidence. The jury were not unwilling to entertain a similar opinion, and so this woman was also acquitted. In another case, that of Mrs. Johnson, who was tried at Liverpool during the Lent Assizes of 1847, before Mr. Baron Alderson, it was clearly shown that deceased had died from the effects of arsenic, and that arsenic existed in the dead body. It was also proved that the widow had purchased arsenic a day or two before her husband's death; that she had been living for some time past on bad terms with her deceased partner; that she had frequently threatened to poison him; and that she had been carrying on an intercourse of gross profligacy with another man. But, notwithstanding these and other aggravating circumstances which were connected with the case, the counsel for the prisoner maintained that deceased had not died from the effects of arsenic, but that the poison had got into the dead body by accident. And he supported his argument by saying, that the grave in which the body lay was a wet one, that there was a great deal of water in the coffin, and that the arsenic had been thus washed from the soil into the dead body. These assumptions, for I cannot call them by any other name, were strongly supported by the Judge, and the prisoner was acquitted.

Case 4.—At the Kildare Lent Assizes in 1847, Jane Mayer and Garret Lennox were tried for

poisoning the family of Dr. Grattan. In this case it was distinctly evidenced that the family had been poisoned by some flummery of which they had partaken on a certain day; that the flummery was made by one of the prisoners; and that the flummery contained arsenic was proved by the testimony of a competent chemist, as well as by the circumstance of its having killed three calves to which it was given on the morning when the members of the Doctor's family were taken ill. Furthermore, it was affirmed, that the prisoners had been heard to declare, that such stuff, alluding to the Indian meal of which the flummery was made, should not be used in the house. And from the evidence of a fellow-servant, Mulligan, there were many other circumstances which bore strongly against the prisoners, insomuch, that when Mr. Justice Crampton was summing up the facts of the case, he said, that if they, the jury, believed the testimony of Mulligan unshaken, as he thought it was, they ought to find a verdict of murder against both parties; but the jury, after deliberating for one hour and a half, returned a verdict of Not Guilty.

In this manner I might proceed until I had recounted almost every notorious criminal case of modern time, not omitting those of Bellamy, Richardson, Allnutt, and Sheridan; but I think you will be enabled to perceive, without the aid of further detail, that there is a manifest indisposition on the part both of judges and juries to convict; and that, in fact, they are too much inclined to listen to the subtilties of ingenious advocates, and too ready to entertain the pleas of coincidence, of accident, and of insanity rather than incur the deep responsibility of dooming a fellow-creature to an ignominious death upon the scaffold.

This leads to the consideration of a sixth point, namely, the license which is permitted to an advocate in a court of law, but we must defer the discussion of this subject until our next lecture.

LECTURES ON MATERIA MEDICA,

DELIVERED AT THE ROYAL COLLEGE OF PHYSICIANS.

By GOLDING BIRD, M.D., F.R.S.,
Materia Medica Professor to the College.

[Reported expressly for this Journal.]

LECTURE V.

MATERIA MEDICA.

MR. PRESIDENT AND GENTLEMEN,—I have now devoted four lectures to the expositions of the views of others, and in endeavouring to bring before you such matters as were worth preserving in our minds, emanating from the intellects of those who have now passed away from us, and which exercised a great influence in the medical practice of those times. The present lecture, and the following one, I am anxious to take the liberty of monopolising to myself. I might otherwise appear to have worn the subject threadbare, and would therefore now devote a portion of the time allotted for this course to the application of remedies which have occupied a prominent position in my own mind. The time has now arrived in which we ought to apply some satisfactory reasoning to the application of remedies; and the views of others having thrown so much light on the *modus agendi* of medicines, we ought now rather to range ourselves under the methodici than the empirici of old; and, while I attempt something in this way, I am not proud enough to suppose that I can advance the science one step, but would at least wish to promulgate certain crude notions. And I would more particularly draw your attention to this subject, chiefly on account of the mind of the Profession having been directed to it on the Continent. I refer to the writings of Messrs. Barth and Dumas—they having at least advanced a step towards pointing out the application of remedies as connected with the treatment of disease. Some of their views are so interesting, and so in consonance with what I have myself observed, that I should be failing in my duty if I did not bring them forward. If I were to point to any one class of therapeutical agents about which there is less satisfaction among Professional men, (with the exception of resolvents,) I should pick out the class called tonic. According to the general signification, almost anything might become tonic—it merely expressing a generic term; and, if you look at the various drugs comprehended under this head, it is curious to observe how many of them are totally distinct,—thus: iron, bismuth, silver, sarsaparilla, gentiana, and serpentaria. Now, I select these as specimens all included under the generic term—tonics, and yet how different their modes of action, and how many practical mistakes occur in their administration. Any particular remedy being *called* a tonic, the patient believes tonic has been given. Thus, the mucous membrane of the ilium may be weak, and because iron is a tonic, therefore iron is given. How often has the practitioner seen cases where the strength deficient, and where the patient has been treated with bitter tonics without any benefit resulting. Much of this failure occurs through want of a due consideration of the particular condition which makes it necessary to give tone to the system. We may be said to have all a series of forces acting within us; these we do not seek to define; but if we could trace disease to their undue action, we should be better prepared to administer our remedies. Now, my object is, to endeavour to throw some light on this matter. If we admit the existence of a vital force, we shall regard the several forces in a different light than those operating on dead matter; in the latter case, there are a series of forces following definite laws, and we can accurately point out their results, and apply certain mathematical laws to them. But not so with respect to the living being; here the force cannot, at present at least, be rendered obedient to certain laws so duly. Therefore, the necessity of studying these forces. All will admit the existence in the body of two great forces,—

1. The vital force—
as opposed to
2. The chemical.

While we admit the first of these, it is obvious, that, unless some cause existed in the body which tended to break up and emaciate, in proportion as we took food, so we should grow on to any size and strength; and therefore it is necessary, at the same time, to admit a chemical force, operating to waste. These forces are antagonistic we know; but they modify each other. Thus—

—v

Growth

Decay

The line *f v* represents the intensity of the vital force, and *c f* that of the chemical. Now in the adult, *f v* is equal to *c f*, and then we should have the line *s f* as the result of the operation of the two forces. If, however, the vital force be more intense than the chemical, that intensity would be represented by the line *v f* becoming longer and inclining to growth; on the other hand, if the chemical force be in intensity, then we should have a lengthening of *c f* and going to decay. This may be a rude attempt at demonstration, but it serves to point out in what manner the forces counteract each other. But there is another series of forces which has been pointed out by Barth and Dumas. In investigating the influence of remedies, these writers indicate the existence of two distinct forces in every organ, and which influence its growth. Thus the *radical* (or *vegetative*) force is inherent to it, and its influence is to induce every organ to carry on its particular function. This is a passive force, or organic inertia. Then there is an active force influencing any particular organ, exciting, diminishing, or modifying its function; and the sum of these two constitute the vital force. Thus, suppose we have a voltaic battery, and the wires be plunged in some electric compound, capable of conducting electricity, the vessels containing the fluid represent the kidneys; the voltaic battery represents the series of organs which developes the principle of life, so far as the nerves are concerned. The battery being ready, but uncharged, is in a passive state; but on filling it with acid, an electric current is induced, which traverses the wires, and produces decomposition; but it also points out the polarised condition of the particles. Now, the current from the battery would represent the active force, and the polarised condition of the particles the radical. It has been thought, that the radical force is excited by the acting force of the battery, and that that action remains, although not in the battery—a polarised condition which keeps up an action, and thus produces a tendency for composition to go on. Then, using this rude analogy, let us suppose a dead body, and that we had the power of lighting up the influence of life. While it was inactive, secretion would not go on; but could we breathe into it the breath of life, what would it do?—at once set up the action of the system, and that force—the nervous influence—would at once be determined to certain organs, and these would resume their function. Now, that there exist these two distinct forces, we have no doubt, for we may control the one without affecting the other. A patient is dropsical; the kidneys do not act; a stimulus is applied, and they perform their function;—the fact is, you have determined the acting force, and thus quickened secretion. On the other hand, you have a patient with gout; the urine is very scanty, —there is hardly any secretion at all, and yet the acting forces are too active, if possible. Here, by giving alkaline salts, what do we do? We do not determine more force to the kidneys, but increase the secretion of urine. As another illustration, we may say, that the acting force is like the influence of steam in the steam-engine, while the radical force acts like the fly wheel. Then it becomes a question—How far we can act on these forces? Take the radical force, for instance. Its intensity differs much: of two individuals, they may have very different degrees of radical forces, and yet be apparently healthy; the one was born of healthy parents, and living in the open country; this one would live long, secrete properly, and live healthy; but another acquires struma. What is the result? We find that his glands secrete unhealthy matter, and then we get the horrors of scrofula. Now, the combined influence of these two forces developes the vital force, or that which is equal to the radical force plus an active force. The combined influence of these determines the healthy state of the patient—*quoad* constitutional health and vigour. Hippocrates distinguished this condition as one beyond which health could not be carried, and the writers above mentioned particularly point out, that there is a point in stimulating these forces, which cannot be exceeded without affecting the health. Thus, if you stimulate a man in fair health, and give him iron as a tonic, if that absorbs, you increase the blood, and he becomes apoplectic or plethoric, with a tendency to hæmorrhage; or if you give a bitter tonic, instead of his becoming more vigorous, you excite the circulation, and produce headache and distress. These writers suppose that Hippocrates alludes to the vital force when he speaks thus in his third Aphorism:—"An extremely full habit of body, in those who devote themselves to gymnastic exercises, is dangerous; for, as it can neither remain in the same state, nor change into a better, it must necessarily become worse. For this reason, it is advisable that the too full habit be reduced, in order that the body may commence a new course of nutrition. But this reduction must not be carried to an extreme, for that would be dangerous; it must be done only as far as the nature of the patient will admit."

Now, these two forces, the radical and the active force, are active in maintaining the status of the body. But there are others, also, which are active in enabling the body to undergo repair. One of the most mysterious of these is the force of assimilation; it is this which has been so erroneously considered as synonymous with digestion. It is not so, however, but widely different. It is a force lighted up by the vital principle, and which enables the individual to cause the pabulum to be assimilated to his own structure. Thus, even in the vegetable world, we have in the same hedge, we find belladonna, night shade, hemlock, the blackberry, and the rosa canina; and we find each one of these absorbing the same fluid from the earth, and yet giving out qualities totally distinct; for instance, we have the hemlock and nightshade developing deadly poison, and the rose and the blackberry giving out citric acid and saccharine matter. This is one of the most remarkable phenomena in nature, and in the human body we see it to perfection; and one of the most important weapons is that which thus helps the physician to control disease. Then we have another—a certain force of vital resistance, which appears to be active in preserving existence and in opposing changes; this is synonymous with the vital force. Taking the views of the two authors, these forces differ to a curious extent in different persons. In some the force of resistance is very prominent; in others that of assimilation is very greatly developed. Thus a person may be to all appearance healthy, florid complexion, and stout; yet he will suffer intensely from heat, he will get chilblains from exposure to cold—he will have fits on bleeding him to one ounce; such a one has very little of the force of resistance, and we also know how distressing it is to treat patients of this character. On the other hand, we may meet with one whose force of assimilation is very small, but where that of resistance is most remarkable. Look at these skeletons, who go through their work, hardly assimilating any of their food, and yet stand all the wear and tear. These are they who go through, under all sorts of influences, and never seem to wear out. Now, this force of resistance is one which we may excite and develope, and one which we may with equal facility crush. A person under the influence of plague, or of typhus poison,—he is at once crushed by it,—chemical decomposition going on even while he is living,—being a mass of bed-sores, and he dies in the most frightful state; here the force of vital resistance is destroyed suddenly. In others this force gradually sinks, as for instance in those under the influence of marsh miasma; here the force is gradually diminished, till at last, on a poison being received, they are crushed, and die immediately, without any particular function being interfered with.

But, after all, what are these forces. Trace them to their one great source, and, undoubtedly, if we look to any part of the nervous system, we should look to the ganglionic system for the origin of them. Admitting, then, the existence of these forces, it is obvious that the definition of "tonic" will admit of a little clearing up. By "tonic," we mean anything which will increase energy. Included under this term are many remedies which widely differ, as arsenic and gentian. But in isolating the conditions in which tonic remedies do good, I shall distinguish them by putting them into two great classes,—the neuro-sthenic or dynamic, that which gives power; and the analeptic or hæmatic, which invigorates by restoring healthy constituents to the blood. Admitting, then, the existence of the forces, and that we have a set of remedies that will increase the vigour of the acting force, and give tone and vigour to the blood, we thus break ground; and, in looking to the class which I call dynamic I would point out the results of my own observation in reference to the action of these remedies. It appears to me that they may be divided into classes distinct from each other,—a division which I have found of very great service to me; if it answers no other purpose it assists a short memory, and I confess mine is of that character. Taking, then, the neuro-sthenic, those which increase the powers of the body, I venture to divide as follows:

NEURO STHENIC—(DYNAMIC.)

SIMPLE—	2. CALMATIVE—	3. NUTRIENT—	4. ANTIPERIODIC—	5. NERVIN—	6. STIMULANT—

From this, I think, we may see our way into the mode in which these act, according to the view which we have taken of the several forces. We talk of bitter tonics as adding to the vital powers; but, in so administering them, we do not so, we only acquire the power of applying a force in a convenient, economical way. If by the whole amount of my physical force I cannot lift this piece of chalk, no human power will enable me to do it without the assistance of a mechanical force. If the chalk is such that I can lift it one foot in a second, no human force will enable me to do more; but, by applying a lever I could lift it indeed higher, but, then, instead of lifting it one foot in a second, it would take ten seconds; so that, as to physical force, we cannot generate it. So here, and with regard to bitter tonics classed under the head "simple,"—to which I shall only allude in this lecture; they possess a crystallised bitter principle, which in all of them is analogous. These peculiar principles are incapable of exerting any particular influence on the secreting organs; but they appear to influence the stomach by increasing its assimilative force. This is the feature of this class of tonics; and I believe they do it by their influence on the vegetative nerves of the stomach, and by causing an increased secretion of gastric juice. In these (the simple) we have a different form of bitter tonics, consisting in the absence of a stringent influence. They owe their value to their crystallised principle, with the exception of the last two, which have not been examined; and when taken, they increase the assimilative force of the stomach—an all-important function, because it is the initiatory stage from which the formation of health blood is derived. Others of these tonics differ in the addition of other influences. The name of the second class is applied to a certain series of dynamics, which, while they increase the assimilative force of the stomach, do more; they act on the extremities of the nerves of the stomach, allay the debility of the organ, and act as sedative agents. The first is the hop; the second is not so generally admitted, but that it exists is certain. If the first is distilled, a certain oil is obtained like opium, and we sometimes meet with persons who cannot bear gentian; so that, in the second class, I isolate one in which the remedies differ from the first in acting as sedatives and thus add another influence to another series of nerves.

ORIGINAL CONTRIBUTIONS.

ON CHOLERA IN IRELAND.

By Dr. KIDD, Limerick.

Since last I had an opportunity of observing on the character of cholera in this country, I have been struck with some experiments of no little interest on electricity in that disease,—experiments, I may say, somewhat accidental in their origin, possibly more worthy of our attention, and likely to throw some light on the spread of the epidemic in this part of the world.

M. Maussenet, I perceive, claims all the honour of discovering that Asiatic cholera arises from some abnormal electric action of the earth; and Dr. Ducros, following out the matter in the spirit of the great Lord of Verulam, has put the thing, he says, to a true *experimentum crucis;* but we are far yet, I think, from a thorough understanding of the precise relationship of these electrical phenomena.

Allowing a very wide margin for this "abnormal electric action" of which M. Maussenet speaks, which he takes the trouble of calling by the very mysterious term—"*terrestro-magnetic;*" and which our other friends of the French Academy would wish to dress up into something very novel and out of the way, it will be well to keep in mind the facts on which he erects his hypothesis. He cannot have read Dr. Adair Crawford's and other remarks on the cholera at St. Petersburgh, and those made in Belgium.

Hasty conclusions from imperfect data, I need scarcely say, have been the bane of the science of medicine, and it we have got at the corner of a fact, very often we take to ourselves credit for a great deal more. We should be satisfied at present to register our observations. The mere opinion is as old as the hills: if our experiments were more general, too, it would be of vast advantage, and lead us ultimately to something like the truth Cholera is, in all probability, depending on some change in the electric state; but, until we have worked out for us the great problem of electric storms and electric calms, as I suppose we must call these phenomena under discussion,—until we understand these things better, we are not much nearer the solution of the mystery. "Much obscurity and confusion," says Dr. Bartlett, "would be removed from our conception of the nature of the philosophy of science, if this long-abused term, *inductive reasoning* could be suffered to disappear; and, if for the indefinite and shadowy ideas it so often expresses or attempts to express, could be substituted those which are so clearly and obviously contained in this phraseology, '*the classification and arrangement of phenomena, and their relationship.*'" This I take is the great source of the success of the great physiological school of Germany.

The tendency of the philosophy of our later school of medicine is very obviously towards a general and very useful eclecticism. We should be additionally, therefore, on our guard, against the admission of indiscriminate phenomena.

The experiments to which I wish to draw attention, being chiefly of a negative character, have led me into this train of thought; they were very simple, I may say, and somewhat accidental.

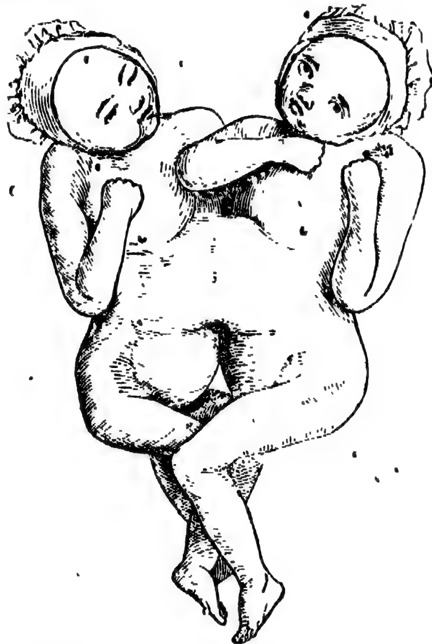
At the period of the decline of cholera in this city, I became anxious to learn the effect of the epidemic on the electricity of the atmosphere. In a very fine large needle suspended freely under glass, the result was actually nil; a few occasional oscillations of no very great moment; in the ordinary magnet the usual diurnal variations, and nothing else. To be more satisfied in the matter, however, a gentleman here—a very particular friend of mine—got up a very splendid magnet (not an electro-magnet) capable of sustaining 70 pounds, which we daily watched. No perceptible phenomena, however, of any kind; and cholera left Limerick: the magnet was laid aside. But now comes the extraordinary fact; on the appearance of the disease in Dublin—the cholera quite gone from Limerick—100 miles east of Limerick, *the magnet quite suddenly lost nearly all its power,* and varies with the decline or increase of the dis

ease in the metropolis. At one time it could scarcel support 10 pounds, and it is difficult to prophec what further changes may take place. I am unwil ling to make any observations, but to leave the fact on record.

Since last I directed attention to the subject o cholera I have been gratified to find I was but anti cipating many of the chief points urged by Dr. Southwood Smith and the Board of Health, whos Report I had not seen till it appeared in the *Medi cal Times*. Not a few of the facts, with which they deal, it is true, lay on the surface, requiring little delving or digging to get at. Others, more deeply mystical perhaps, they have brought into a some what clearer light, while others have been scarcely touched. The entire Report I think a documen containing many very sound and important con clusions.

Every one, indeed, not wedded to a favourite theory, if he have any experience of the malady at all, must perceive that sanitary measures—not qua rantines, in any shape or guise—constitute the true means of guarding against diseases like cholera, and that as, in a public capacity, we countenance either one or other of these measures, we run a chance of banishing this frightful plague from our shores or naturalising it amongst us. Remove those crying errors in our sanitary arrangements, in fact, that abound in all our overcrowded towns and villages, and we take away that by which the disease exists and propagates itself.

The epidemic influence that we so dread is, when rightly studied, not that formidable thing we had been taught to think—we ourselves, perhaps, in our mistaken notions,—the chief cause of its con tinuance. I spoke before of these causes at work— one, of possibly electric origin, the other local. Every day's experience makes me more satisfied of the truth of this view of the disease—facts of an ochletic character. Cholera hanging about crowds of people can in no other way perhaps be explained. Another point not less evident is this, that the more this *ochletic element* predominates, the more the disease, like hospital gangrene and some others, puts on the semblance of contagion, till very often, in mere reasoning on cases, it is difficult to divest the mind of the idea of contagion. At the other side of the Atlantic, I perceive the men of New York are pre cisely of this opinion also.



The subject of quarantine and that of contagion, though often mixed together, too, are, of course, different and distinct. If epidemic, no *cordon* mis named sanitary, can have any effect in warding off a specific disease. We should not, however, include under epidemic as contradistinguished from con tagious diseases, which are possibly one and the other. The contagiousness of typhus has been, I think, quite clearly underrated by the Board of Health; nor can I say I quite agree with the opinion, that, whereas disease cannot be imported in bales of *new* cotton, it cannot in *old* clothes—the miserable rags, for instance, of our poor people at this side of the channel emigrating to England and America. Every one here has seen typhus go from one to one of a family for months and months in wretched hovels, which the pen of "S. G. O." could scarcely describe—aye! visit every mem ber of the household two and three times apiece till it would be a mercy to pull such a plague-spot down; go on for months and months; die out and revive, and go on again through a second series of wretched beings. Here it would be idle to deny that some very palpable and fearful agent was at work. That a certain epidemic constitution of the atmosphere is necessary for this species of fever, too, as well as cholera, the entire history of our Irish epidemics very fully testifies. Here defect of sanitary matters is so perceptibly the chief agent at work, that the epidemic tendency is lost sight of; but the "family likeness," so to speak, of cases at particular epochs, at once exhibits the epi demic influence; at one time the skin, at another some particular points in the intestinal tract; in a third season, the lungs and so on, being almost in variably attacked.

If an absence of electricity, or any change or dis turbance of this wondrous agent be the chief thing at work in our epidemics, it is satisfactory to b assured of the fact. We are not, however to jum to the conclusion that it is also a cure. For mysel I must profess a more lively faith in Dr. Stevens plan, from all the evidence we have of its efficacy to the mere applying of wires over the solar plexus We should recollect that if this absence of electricit be the real agent, in addition to its diminishing th nervous supply from these centres—granting suc a thing, that it has previously assisted in deranging the nicely poised elements of the atmosphere. W are, indeed, but on the threshold of the inquiry and until we get more data, we should abstain from building up very tottering and insufficient theories.

AN ACCOUNT OF THE "FLEMISH TWINS," TWO INFANTS UNITED BY THE ANTERIOR WALL OF THE ABDOMEN.

By Dr. VERHAEGHE, of Ostend.

On the 27th of May last, there was born at Er neghau, a village situate about four leagues from Ostend, a double monster (of which the accompany ing engraving is an accurate sketch); which, ac cording to the classification of Geoffrey St. Hilaire, belongs to the family Monomphalia (*one navel*), and to the genus Xiphopaga (*xiphoid* - [*cartilage swelling*).

It consists of two bodies, which are perfectly dis nct, but are united together in that extent of the bdominal parietes comprised between the xiphoid artilage and the navel. This junction is not formed y a species of band or tie; on the contrary, it con ists of an intimate fusion of the abdominal parietes f one infant with those of the other. The xiphoid artilages are curved forwards and sideways, ap roaching each other so as to unite by their sum its and form an obtuse angle. The umbilicus is ngle for the two children, and is situated at the ottom and on the anterior part of the inferior com issure of this junction. The extensibility of the arietes of the belly allows of the children being laced, the one on the right flank, and the other on he left, so that they look obliquely at each other. n consequence of this extension of the abdominal arietes, they can be made to take the appearance f a large band, or of a means of union like that of he Siamese twins.

The most natural position, and that in which the oint of junction experiences the least tension, is hat in which the two infants are turned face to face nd belly to belly; but, as we have just said, the xtensibility of the abdominal walls permitting them o lie obliquely, almost side by side, it is in this osition that they are habitually found.

This union does not constitute a simple juxta position, as one might at first be disposed to think; but there is a true and intimate fusion of the epi gastric parietes, and very probably (not to say cer tainly,) a communication of the abdominal cavity of the one with that of the other. In point of fact, the seat of the junction is resisting and elastic in all its parts; and percussion gives *everywhere* a very clear tympanic sound,—a fact which proves that beneath the finger which percusses there are hollow viscera, filled with gas (either stomach or intestine, or, perhaps, both these together). The height of this union is 68 millimetres, or about two inches English, and its thickness from before backwards is 38, or 1½. The circumference of the two bellies thus united is 47 centimetres, or about 14 inches.

The children, who are of the female sex, are well developed, nevertheless their bodies are rather small in size; the four arms and legs are equally developed respectively. There is no concord of the functions: each has a separate life; so that often the one sleeps while the other is crying and weeping, or the one eats and takes the breast while the other continues sleeping.

So also the act of defecation does not occur si multaneously in both. Syrup of violets given to the one provokes evacuations of a deep green colour; while the stools of the other are devoid of this coloration, and *vice versa*,—a fact which suffi ciently demonstrates that each of them has a dis tinct digestive apparatus.

The parents are of good constitution, and belong to the class of day-labourers. The father's age is 44 years, the mother's 38; they have previously had three children, whereof one is still living. The mother states herself to have experienced nothing at all remarkable during pregnancy.

The labour lasted a long time, and the expulsive pains were very severe. The child on the right was the first to be expelled, the head presenting: the other followed five minutes after; but, according to the midwife's statement, its feet came first. There was but one navel-string and after-birth.

These truly curious beings, whom we propose to designate "*The Flemish Twins*," have received names, the eldest that of Marie, the youngest Sophie. They continue to enjoy good health, and everything promises that they will continue to live.

The question has been proposed to me as to whether it would be possible to separate them by an operation; but the results furnished by palpa tion and percussion of the seat of junction give a strong presumption of a communication between the two abdominal cavities, and have thus dictated to me an answer in the negative.

CASES OF PLEURISY WITH EFFUSION INTO THE LEFT SIDE OF THE CHEST AND DISPLACEMENT OF THE HEART.

By C. J. B. ALDIS, M.D.,
Fellow of the Royal College of Physicians, and Lecturer on Medicine at the Hunterian School.

1. A CASE OF LATENT PLEURISY.

I first saw the gentleman, Mr. P. H., with Mr. Scatliff, of Sloane-square, on Wednesday, March 7th, 1849, when the pulse was 120, compressible, the pa tient lying on his back, but can lie on either side indiffer ently; no orthopnœa; slight cough, no expectoration; the heart beating to the right of the sternum as far as the right nipple; left side of the thorax immove able; breathes only with the right lung; intercostal spaces of the left side of the chest effaced; dullness on percussion over the whole of the same side; re spiration inaudible; no ægophony. Suffered from hæmoptysis to the extent of about a pint about three weeks previously, when he was in the country, at which period he consulted a medical practitioner and came to town, having travelled by night in a second class carriage for five hours. After his return he ex perienced pain in the back with occasional dispnœa. He occupied his mind with chemistry, and enter tained no idea of the extent of his complaint until Mr. Scatliff examined his chest on Monday, March , when he observed symptoms similar to those which I have described. It was remarkable, that the patient had been actively engaged in his occu-

pation with scarcely any inconvenience, in fact, he appeared to be in good health, excepting occasional shortness of breath. The treatment consisted of small doses of hydrarg. chlorid., haust. nitri., cum tinct. digitalis, and blisters.

March 20.—Was visited by Dr. Hodgkin, Mr. Scatliff, and myself, the former of whom confirmed the diagnosis of the two latter. The symptoms continued much the same as before; the pulse varied from 80—90. The patient took dec. sarsæ, c. sp. æth. nitric, and lin. camphor. was to be rubbed all over the affected side of the chest, and he was to be confined to his bed.

He was subsequently visited by Dr. Hodgkin, Dr. Sibson, myself, and Mr. Scatliff; the effusion gradually diminished, while the heart was returning nearer to its natural position. Dr. Sibson noticed the following symptoms by means of his chest-measurer. The first time I saw Mr. H. the expansion of the ribs on the left side was *nil*, while that of the ribs of the right side was double the amount, or from 8—20 100ths of an inch; the abdominal motion was rather more than normal in the centre, being 35 100th inch at the left side; it was only 2 or 3-100th, instead of 10. To make up for this, the motion was 20, 25, or 30-100th, instead of 10 on the right side of the abdomen. At the next examination the effusion was lessened. There was some shade of motion on the second left rib about 1 or 2 100th; the abdominal motion on the left side was decidedly increased, being from 4-6, while the exaggerated motion on the right side of the abdomen was diminished, being about 15—20-100th. The movement of the whole right side was scarcely so exaggerated as on the previous occasion. During a deep inspiration the ribs on the right side expanded about 60 or 70-100th. Those on the left side, over the 2nd to 4th or 5th, expanded about 35-100th inch; over the 6th and 7th ribs, the expansion was inconsiderable. On the 26th of May, the line of dulness just to the right of sternum, effusion lessened, heart's beat felt both to the left and right of the sternum. The following were the respiratory movements in 100ths of inch :—

	Right.	Left.
2nd rib, ordinary inspiration	15-20	5-10
Deep inspiration . .	80	45
5th rib	6-10	0-4
	40	15
6th rib	5	0
At the side	30	10
9th	10 15	0
	55	20

ABDOMEN.

	Centre.	
20	40	10

Being a marked advance towards the normal state. The patient is at present in the country.

CASE OF EFFUSION INTO THE LEFT SIDE OF THE CHEST, IN WHICH PARACENTESIS THORACIS HAD BEEN PERFORMED ON BOTH SIDES.

The patient's name was Silas Hann, aged 21, a tailor residing at Lambeth, and became an in-patient of St. George's Hospital under Dr. Chambers, on Dec. 28, 1833. Pulse 120, soft; skin warm; bowels open; urine scanty, with yellowish sediment. Complains of shortness of breath, aggravated by exertion; no palpitation; cannot lie on his left side on account of cough; cannot expand the thorax; both sides dull on percussion; was in the Westminster Hospital twenty-four weeks; left it about a month ago; paracentesis thoracis was performed between the sixth and seventh right ribs three days after admission into that institution—fluid drawn off is said to have been transparent; heart beating on the right side of the sternum; ailing six months; attacked first with weakness and cough; has had slight hæmoptysis since the operation.

℞ H. cetacei c. potass. nitr. gr. iiij.; tinct. scillæ ♏ xv.; sp. æth. nitrici ʒss. sextis horis.

℞ Pulv. ipec. c. gr. viij.; hâc nocte.

Dec. 30.—Subaxillary region of both sides dull on percussion; not affected by change of posture.

Jan. 6, 1834.—Chest exceedingly dull on percussion on both sides up to the level of about the fourth ribs; respiration inaudible in the same situation both anteriorly and posteriorly. I cannot detect any ægophony. Heart felt beating to the right of the sternum, and its sounds heard more distinctly on the right than left of sternum. Rep. haust.

℞ Pilul. hydrarg. gr. iij.; scillæ exsiccat. gr. i.; digitalis gr. ss., ter die.

10th.—Feels very faint; thinks he has made rather more water; less fluid in the left side; pulse small and frequent; skin warm and moist; tongue whitish.

℞ Pil. hyd. gr. iss.; scillæ pulv. gr. i.; ext. colch. acet. gr. ss., ter die.

℞ Haust. hydrocyan.

℞ Pil. sapon. c. opio, gr. v. o. n.; app. emp. canth. amp. lateri sinistro.

13th.—Passed a bad night; feels easier this morning; lying on the right side; no orthopnœa; breathing much relieved; the level of the dull portion of left thorax on percussion is lower; heart's action less violent and less evident than it was to the right of the sternum, but more so on the left.

Feb. 11.—Paracentesis thoracis was performed yesterday between the sixth and seventh ribs of the left side, at their angles, that part of the chest being rather prominent. About two pints and a quarter of transparent fluid, light brown, with a greenish tinge, were drawn off. It coagulated by heat and nitric acid into a solid mass. The patient felt considerably relieved after the operation; but to-day complains much of difficulty of breathing and pain about the heart. Pulse 140, very small and weak.

12th.—Died at three a.m.

13th.—*Sectio Cadaveris.*—The body, before being opened, was succussed, and fluid distinctly heard in the left side of the chest. On removing the sternum there were found about two pints of fluid, similar to that which was drawn off, and frothy from the succussion in left pleural cavity. The pleura had a deposit of hard cartilaginous lymph, varying from one-eighth to one-fourth of an inch in thickness over its whole extent, which, in some parts of the pleura cortalis, presented a slightly reticulated appearance. The lung was compressed into a small compass against the mediastinum and apex, and firmly bound down by the thickened pleura. The deposit could be peeled off from the pleura pulmonalis, leaving an apparently healthy serous surface beneath. On the right side there was a very thick deposit between the lung and the ribs, with universal and firm adhesion, so that it was necessary to separate it with the knife. The lung was then cut across transversely at the level of its root. In this situation the deposit on the exterior of the lung varied from one-half to three-quarters of an inch in thickness, and had the appearance of five laminæ, a purple layer in the centre, then a white one on either side, and again a purple lamina externally. Vessels were distinctly observable running from one to the other on separating them. These deposits extended over the whole lung, but were not always found in these regular laminæ. The white deposit in some parts had a complete tubercular appearance (like that of Dr. Baron's tubercular accretions).

The heart was considerably more to the right than natural, and was bound down in that situation by the thickening and adhesion of the anterior mediastinum. It was very small. Pericardium healthy, and contained about the natural quantity of serum.

1, Chester-terrace, Chester-square, July 7, 1849.

PROGRESS OF MEDICAL SCIENCE.

FRANCE.

(From our own Correspondent.)

THE CHOLERA.

With deep satisfaction I have to announce to ou the disappearance—at least official—of epidemic cholera from Paris. The number of cases within the last few days has been so insignificant, that Government has ceased to publish official returns of the mortality. We are thus freed from a most unwelcome visiter, and you from a subject which threatened to become tiresome in its monotony. This will probably be my last notice of the disease.

The weekly mortality does not exceed 263, distributed thus—

	Deaths in City.	Hospitals.	Total.
June 28th	23	16	39
29th	34	13	47
30th	23	19	42
July 1st	23	12	35
2nd	16	10	26
3rd	4	14	18

The number of deaths in the military hospitals, during the same period, amounted to 16, making a total of 203. Finally, the deaths in hospitals do not now exceed six or eight per day, and in the city the disease has nearly disappeared altogether. Indeed, it is a remarkable fact, that the total mortality of Paris—even including deaths from cholera—is much below the average at the present moment, and that the deaths from various causes increase as those from cholera diminish. One is reminded of Ulysses' answer to Polyphemus.

Thus we have—

	Deaths from Various Causes.	From Cholera.
29th	22	34
30th	48	23
1st	48	21
2nd	46	16

while the average mortality of Paris is between 70 and 80 per day. Perhaps it is, that all the weakly subjects have been removed by the disease.

The atmospheric temperature has certainly no influence on this fortunate result; for at the moment I write the heat is overwhelming. Chevalier's thermometer on the *Pont Neuf* indicates 28½ centigrade in the shade,—a temperature equal to that of the hot bath, and warmer by eight degrees than the average temperature of Algiers.

The prospect of the speedy extinction of the disease, renders it, perhaps, less incumbent on us to record the various specifics and modes of treatment which are daily proposed, and many of them by men who ought to know better. M. Worms, one of the Physicians of the Military Hospital of Gros-Caillou, speaks in the warmest terms of the efficacy of an acid treatment. It is true, indeed, that his experiments were confined to comparatively mild cases. The remedy employed by Dr. Worms was, he informs us, the "mineral lemonade," (the French, you see, can make *bulls* as well as other people,) composed of twenty grammes of dilute sulphuric acid to two pints of water. Dr. Worms endeavours to explain the efficacy of the "acid treatment," on the supposition, that asiatic cholera is a pestilential exanthema, excited by emanations, which modify the electric phenomena of the body, and cause an almost absolute predominance of the *alkaline* principle in the blood, with suppression of the *acid* element.

Unfortunately for this doctrine, the researches of Dr. O'Shaughnessy have demonstrated exactly the reverse. M. Piorry, on the other hand, with whose medical eccentricities we have been long familiar, attributes the fatal result of cholera to a deficiency of water in the blood. As it would be useless to introduce the fluid into the stomach or lower bowel, M. Piorry hit on the ingenious idea of throwing it up into the bladder. A subject was soon found. "The veins (says Professor Piorry) were empty; the arteries nearly pulseless; the heart and liver diminished by one half in size (!!!); the lungs excessively sonorous, and the abdomen charged with fluid. Nearly two pints and a half of water were thrown up into the bladder within an hour. By the plessimetre it was ascertained that absorption took place rapidly; for, as soon as the bladder acquired a certain size, it diminished by absorbing the fluid. At the same time the veins became filled, the pulse was firmer, the heart and liver increased in size, and the patient's state was greatly meliorated."

What became of him ultimately the "Chronicles" say not; but he is probably with the "Capulets."

MUSCULAR ACTION AND ELECTRICITY.

At the last meeting of the Academy of Sciences, M. Arago read the following note from the illustrious Humboldt, relative to the above interesting subject:—

"Neither the jeers of certain editors on German credulity, nor the negative results obtained by two of our first natural philosophers, have changed my convictions regarding the influence of muscular action on the movement and direction of the galvanic needle. We have recently repeated our experiments at M. Reymond's, and I invited M. Mitscherlich to attend, knowing his great dexterity in the management of delicate instruments. On giving tension to the muscles of the left arm, the needle was instantly made to move by M. Mitscherlich; and that in the direction predicted by M. Reymond, viz., one indicating a current from the hand to the shoulder of the arm which was in action. On stiffening his right arm, M. Mitscherlich made the nee le move in an opposite direction, and traverse a smaller number of degrees; this arises from the fact, that the energy of muscular contraction is not always the same in both arms. Occupied, as I have been, for more than half a century with physiological researches of this kind, the discove y of M. Reymond has deeply interested me. It is a vital phenomenon, rendered sensible to us by an instrument of physics."

In connexion with the same subject I may mention the result of some curious experiments recently made by M. Ducros. The conductors of a galvanometer were applied, one to the forehead, the other to the neck. The needle remained steady and marked forty degrees. The patient's thigh was now strongly pinched and, under the influence of the pain, the needle passed to eighty degrees with great rapidity. The experiment, frequently repeated, gave the same results, and M. Ducros hence concludes "that all causes which increase vital activity react on the galvanic needle at a distance from the point of their immediate action."

PARALYSIS OF THE BLADDER CURED BY GALVANISM.

An interesting case of this kind recently occurred in the practice of M. Monod, Surgeon to the Maison de Santé. A woman, fifty-seven years of age, labouring under an incurable disease, endeavoured to commit suicide by means of charcoal fumes. She was relieved in time, but an obstinate paralysis of the bladder remained. M. Monod suggested a trial of galvanism to the neck and fundus of the bladder. On the first application the patient was enabled to make water without assistance, and her recovery was rapid.

NEW INSTRUMENT FOR PILES.

M. Amussat has invented a new instrument for the eradication of these troublesome companions. It is a small forceps, somewhat like a dissecting forceps. The points, or rather the branches, for one-third of their length, are split, and receive two small hollow cylinders, which are charged with Vienna caustic at the moment of operation. The branches of the forceps are brought together by a screw, and the base of the pile attached by constriction and cauterisation conjointly. When the instrument has acted for some time, a jet of cold acidulated water is directed on the part, to remove the superfluous caustic and allay the sensation of burning. M. Amussat has already applied his instrument in practice with complete success.

A NEW DISINFECTING FLUID.

The Sanitary Committee, or Board of Health, recently appointed, has just made some interesting experiments, which are worthy of record.

You are well aware of the deplorable state of the water-closets and other *lieux d'aisances* in this capital of the civilized world. Although Paris had made considerable progress, within the last ten years, in the improvement of these most necessary sanctuaries, their condition still remains barbarous, particularly in the numerous schools devoted to the reception of the children of the poorer classes. The charity schools of the Rue Brise, Miche, and two other establishments of the same kind—regular pest-houses—were handed over to MM Audiat and Labolonye for the purpose of making some experiments with a new disinfecting liquor,—a solution of nitrate of lead. The cess-pools alluded to, I may remark, were so infected that it was impossible to approach them without being almost suffocated, while the ammoniacal vapours penetrated through all the class-rooms, rendering their habitation intolerable. A simple washing of the infected localities with the disinfecting fluid, and a few aspersions, completely removed every trace of disagreeable odour. The experiments were continued for fifteen days, and the Board ascertained that no development of obnoxious smell occurred before the third day, when it was easily suppressed by a fresh application of the fluid. The Board of Health announces its conviction, from these and other experiments, that we now possess a means of completely disinfecting all *lieux d'aisances*, and it has formally invited the Corporation of Paris to take immediate steps for applying this principle to the purification of the numerous charity schools and asylums throughout the city. The nitrate of lead possesses a much greater disinfecting power than the chloride of lime. It might, perhaps, be well to compare its powers with those of the chloride of zinc.

SCOTLAND.

[From our Edinburgh Correspondent.]

At the Meeting of our Medico Chirurgical Society, on the 4th current, Dr. Hughes Bennett read a Paper on the local treatment of Chronic Eczema and Impetigo. The design of the Paper was to point out the efficacy of a simple plan of local treatment which he had found successful in several cases of long standing. After noticing the frequent connexion of the acuter forms of eczema with constitutional disease, or derangement of the general health, as with strumous tendency in the young, and, in after life with dyspeptic disorder and the oxaluric, phosphatic, or uric diathesis, he laid it down as a rule that generally, in proportion as eczema becomes more chronic, it is the less dependent on constitutional disturbance. The form of eczema in which the simple treatment he had to recommend had been so successful was eczema with impetigo in a chronic state, or the chronic form of what dermatologists term eczema impetiginodes. Dr. Bennett distinctly regarded this disease not as a mere form of eczema, approaching by its subsequent effects on the integuments to impetigo, without losing its vesicular character, as Bateman taught, but as a combination of the two diseases, an intermixture of the vesicles of eczema with the pustules of impetigo; an idea which the last named author hints at, but hardly adopts as the character of his species impetiginodes,—the truth being, that the co-existence of two or more cutaneous diseases on the surface at once is an observation which it has required time to mature. He dwelt particularly on the obstinacy of eczema impetiginodes when it affects such parts as the seat of the whiskers, the beard, or the pubes. He seemed inclined to regard the *crusta lactea* of authors as an eczema impetiginodes of the face. He said, that the simple treatment he had found so successful probably did not differ much from mere water-dressing; but he had to state the facts as he had observed them. This treatment consisted in the continued, not the mere occasional application, of a weak alkaline lotion to the affected part. Two drachms of subcarbonate of soda were dissolved in a pint and a half of water, and lint wet with this lotion was kept in exact contact with the eruption, evaporation being prevented by a covering of oiled silk or gutta-percha cloth. In proof of the efficacy of this simple treatment, Dr. Bennett recounted several obstinate cases; one in which the disease had affected a gentleman's face at the roots of a thick black whisker; this disease had lasted for a long time, but began to yield as soon as the patient consented to the removal of the whisker, so that the lotion might be applied exactly to the seat of the eruption. In a second case the disease was seated at the roots of the beard, and this also was cured as soon as a proper mode was fallen upon of adjusting the wet lint to the part. In a third case, the disease was on the pubes and adjacent parts, and had resisted some of the ordinary modes of treatment for eight years. The cure in this last case was more tedious, owing not merely to the obstinacy of an affection which had lasted so long, but also to the difficulty of complying with the requisite conditions of the treatment, owing to the extent and inequality of the surfaces where it had its seat. But within three months from the commencement of the treatment the disease had entirely disappeared. Dr. Bennett attributed the cure in these cases wholly to the local treatment, though in the first the arsenical solution, in small quantity, had been employed simultaneously for a short time, and in the last the patient had gone to Harrogate, and used the waters before the complaint had altogether disappeared. In some of the cases in which the crusts were particularly thick, poultices were applied before the lotion was resorted to.

A short discussion followed, in which various remedies were referred to. Dr. Maclagan, sen., who was in the chair, agreed with Dr Bennett, that ointments were generally unserviceable in chronic eczema, and approved of his treatment, particularly in so far as it included the plan of the water-dressing. Dr. John Gairdner spoke of the beneficial effects of the iodide of sulphur, twenty-five grains to the ounce of lard, as suggested by Biett, and formerly recommended to the Society in ecyema, by the late Dr. Hay. Dr. G. Paterson spoke in favour of the treatment proposed by Dr. Neligan, of Dublin, as analogous to that recommended by Dr. Bennett. Dr. William Gairdner detailed the method of using the flesh brush, as practised in some of the Parisian Hospitals. Dr. Fleming referred to the dry treatment by wheat-flour, practised by Devergie in certain forms of eczema, which disagreed with every kind of lotion, and doubted if Dr. Bennett's plan would have very extensive success. He considered the plan defective as a rational method, since alkaline applications must destroy the natural sebaceous secretion of the skin, and instanced the case of washerwomen, who were subject to eczema, from the effects of the alkali of the soap on their hands and arms. Dr. Bennett contended that but a comparatively small number of washerwomen were ever affected with eczema, and that, if the alkali of the soap was hurtful to them, it was owing to its being allowed to dry successively on the surface, and so to irritate. He maintained that the general effect of alkaline applications in cutaneous diseases was not irritant but sedative, diminishing tingling, itching, heat, and other uneasy sensations. Dr. Douglas Maclagan insisted on the necessity of examining the state of the urine in every case of obstinate cutaneous disease; and Dr. Bennett mentioned that immediately after Dr. Begbie's late paper on oxaluria was read before the Society, crystals of oxalate of lime had been sought for and detected in the urine of a patient in the clinical wards, affected with obstinate lichen, and that on the use of nitro-muriatic acid the disease had quickly disappeared.

Mr. Struthers next read a short paper, illustrated by diagrams, on the use of the oblique muscles of the eye. Mr. Struthers described the motions of the eye as consisting of a series of rotations on different axes, namely, the vertical, the transverse, the oblique, and the intermediate, adding that the eye had besides the power of rotation on the optic axis, which, in reference to the eye itself is the antero-posterior axis. The design of the paper was to show, by considerations drawn from comparative anatomy, that the use of the oblique muscles is to produce rotation of the eye on its antero-posterior axis. He pointed out the disposition of the oblique muscles of the eye in the three inferior orders of the vertebrata, as necessarily leading to the inference, that, in that portion of the animal kingdom, such is the office of these muscles. Inasmuch as in birds, reptiles, and fishes, the oblique muscles arise in common from the inner side of the orbit to pass in a diverging manner, the one upwards and outwards to the upper, the other downwards and outwards to the under surface of the eyeball, that this must be regarded as the normal plan of the oblique muscles; but that in mammals these muscles have virtually the same disposition, since the

trochlea at the inner part of the orbit is, in effect, the fixed point towards which the eyeball turns when the superior oblique acts. The practical conclusion drawn by Mr. Struthers from this view is, that the division of the inferior oblique muscle, as proposed by some in certain forms of strabismus, must be totally useless.

The plan of the paper did not lead the Author to the consideration of the physiological uses of the rotation of the eye on its antero posterior axis. Neither did he attempt to show why, in the case of the superior oblique muscle, there is a deviation in mammals from what he considers the normal disposition of the muscles as displayed in the structure of birds, reptiles, and fishes. It is, perhaps, quite correct to say, with Mr. Struthers, that the normal disposition is exhibited in these three inferior orders of vertebral animals; yet the development of the same muscles is plainly higher in mammals,—the superior oblique in the latter being rendered more efficient for its purpose, whatever that purpose may be, by being made of greater proportional length. The subject is plainly one of considerable interest, and has a practical bearing beyond the subject of strabismus, since the division of one or other of the oblique muscles has been believed, among other kinds of mystery, to be useful in myopia,—among the authorities for which, it may be remembered, are Adams, in this country; Bonnet and Guerin, in France.

AMERICA.

ON THE ARRANGEMENT OF THE AREOLAR SHEATH OF MUSCULAR FASCICULI AND ITS RELATION TO THE TENDON.

Dr. Joseph Leidy writes (in the proceedings of the same Society):—Well known is it, that the fasciculi of fibres of the muscles are surrounded by sheaths of areolar tissue, but the arrangement of the filaments of fibrous tissue forming the sheaths, and their relation with the tendon, I think has not been properly pointed out. From repeated observation, I have found that the filaments of fibrous tissue cross each other diagonally around the muscular fasciculi, forming a doubly spiral extensible sheath. None of the filaments run in the direction of the length of the fasciculi, and but few are transverse. Many of the filaments of the sheath form an interlacement in the same diagonal manner with the filaments of the sheaths of neighbouring fasciculi. This arrangement is readily distinguished, if several fasciculi be drawn slightly from each other upon a plate of glass, and the intervening areolar tissue viewed beneath the microscope. When the filaments reach the rounded extremities of the fasciculi, they become straight, and in this manner conjoin with the tendinous filaments originating at the extremities of the muscular fibres. The importance of this arrangement can be readily understood; from the diagonally crossing course of the areolar filaments, comparatively inelastic in themselves; the sheath is rendered elastic, thus permitting the muscular fibres freely to move without their action being interfered with, while at the point of attachment of the fasciculi, where any elasticity would be worse than useless, from the fact that part of the muscular action would be lost in the mere extension of an elastic substance, we find the filaments arrange themselves so as to become part of the inextensible tendon.

SPURIOUS CHEMICALS.

The *Pharmaceutical Journal* remarks, that a system appears to have prevailed to a considerable extent, not of adulteration, but of the wholesale substitution of comparatively worthless compounds, for valuable and powerful medicinal agents. Within the last few years compounds of valerianic acid with oxide of iron, with oxide of zinc, and with quina, have been introduced into medical practice as efficacious remedies, especially in hysteria, and other affections of the nervous and uterine system, and in fevers.

Citrate and tartrate of iron, flavoured with a few drops of oil of valerian, has been extensively supplied for valerianate of iron; and acetate of zinc, flavoured in the same way, has been substituted for valerianate of zinc; and these spurious compounds have been sold at prices which, although defying competition on the part of the genuine valerianates, have nevertheless been twenty or thirty times greater than the commercial value of the substituted articles. For valerianate of quina the disulphate of that base, with a little oil of valerian to disguise it, has been in like manner substituted.

The means of detecting the frauds are as follows:

1. *The true valerianates* have a sour, disagreeable, and very persistent, although not powerful smell, which is essentially different from that of oil of valerian.	1. *The spurious imitations*, being flavoured with oil of valerian, smell strongly of that substance.
2. *The true valerianate of iron* is almost entirely insoluble in water; and the valerianate of quina fuses into oily globules in boiling water, and dissolves with difficulty. They are both freely soluble in spirit.	2. *The spurious valerianate of iron* is perfectly soluble in water, especially when aided with a little heat; it is insoluble in spirit. *The spurious valerianate of quina* is soluble in about thirty parts of boiling water, and, as the solution cools, it is deposited in acicular crystals, which have the bitter taste and other characters of disulphate of quina.
3. *The true valerianates*, when mixed with a little diluted hydrochloric acid, are decomposed, and the valerianic acid being set free, rises like oil to the surface of the liquid. To get this character it is necessary to operate upon from five to ten grains of the specimen, and to avoid the use of too much of the diluted acid, as valerianic acid is soluble in about thirty parts of water. The liberated valerianic acid has the sour, disagreeable, and very persistent smell, which to a slight extent is perceived in its salts, but it is readily distinguished from that of oil of valerian.	3. *The spurious valerianates*, when added to water, will generally yield a thin film of oil, which floats on the surface, and is easily detected as oil of valerian. On heating the liquid this oil is driven off, without otherwise decomposing the salt, and no further indication of valerian will afterwards be obtained. On treating them with diluted hydrochloric acid there is no valerianic acid set free.
4. *The true valerianates*, when mixed with a little proof spirit, and one-fourth the volume of oil of vitriol is then carefully added, will yield valerianic ether, which is recognised by its agreeable fruity smell, somewhat resembling that of the pine-apple. This ether can hardly be distinguished in smell from butyric ether.	4. *The spurious valerianates* yield no valerianic ether; but the *spurious valerianate of zinc*, when treated as above, yields acetic ether, which is easily detected.

The foregoing tests are sufficient to distinguish the true valerianates from the spurious substitutes above-mentioned; but there is reason to believe that other substitutions have been practised, although not so extensively. We have met with a specimen of so-called valerianate of iron, which is evidently not what its name indicates, and yet it contains neither citrate, tartrate, nor acetate. It is in the form of a brown powder, insoluble in water and in spirit. It smells of valerianic acid, but, on being decomposed with hydrochloric or sulphuric acid, yields no appreciable quantity of the oily product. We have not had time to submit this specimen to a careful examination, but it is easily distinguished from the true valerianate of iron by its being insoluble in spirit, while the latter dissolves freely in this menstruum, even without the application of heat. This suspected specimen is also distinguished from the genuine by its behaviour when heated in a platinum crucible.

The true valerianate, if carefully heated, fuses, gives off valerianic acid undecomposed, then as the heat is increased, burns with a luminous flame, and emits very offensive odour.	*The suspected specimen* does not fuse or give off any appreciable quantity of valerianic acid. The vapour does not readily inflame, and the odour emitted is not offensive.

The residue of oxide of iron is the same in both specimens, namely, twenty-five per cent., and the acid originally present is organic.

Where mere adulteration is practised, the detection of the fraud is much more difficult than it is in the cases to which we have hitherto alluded, the cupidity of the manufacturer having fortunately, in these cases, blinded his discretion, so that a speedy exposure of the practice was inevitable.

TO SUBSCRIBERS.

The remainder of the Index, and the Title to Vol. XIX., are given in this Number; which, as well as the preceding one, contains an additional eight pages of print. Subscribers in want of any of the back Numbers are recommended to complete their sets.

Cases for binding the volumes, price 2s. each, are now ready for delivery. Portfolios, for preserving the weekly Numbers, price 3s.

New Subscribers will oblige by forwarding their Names direct to the Office, 147, Strand, or to the News Agents or Booksellers. All Post office Orders should be made payable to the Publishrse WM. S. ORR AND CO.

THE MEDICAL TIMES.

SATURDAY, JULY 14, 1849.

We lately took occasion to offer, in our editorial capacity, some few remarks on the maladies which formerly prevailed and committed such fearful ravages among our population; and, reflecting on the once marshy, partially cleared, and uncultivated state of the country,—on the close, confined, dirty, and unventilated condition of the narrow streets of the cities,—we arrived at the conclusion, that we need be at no loss to ascertain the sources whence these diseases sprang; and then, considering the present improved condition of the country at large, the admirable police of our cities, and the active, intelligent, and industrious habits of the people, we ventured to express our conviction, that, since many diseases had totally disappeared from among us, and others been greatly mitigated, so also those of the present day, fatal as they were, would, in like manner, fly before the advance of science. We will now take a view of the other side of the picture, and inquire into the truth of the assertion, that disease has increased with the progress of civilization. There can be no doubt, that too luxurious living,—idleness, intemperance, mental exertion, agitation, and strong excitement, worldly cares, the fluctuating nature of commercial speculations and the continued struggle to meet the daily and accumulated wants of an excess of refinement,—give rise to many diseases. We accordingly find, that gout, apoplexy, palsy, melancholy, lunacy, dyspepsia, with a train of complaints generally denominated nervous, are among the maladies which have increased. Since the beginning of the eighteenth century, out of every 21,000 deaths, from 2,000 to 3,000 have been cases of apoplexy or palsy. Gout is more prevalent than formerly; and cases of dyspepsia, or stomach complaints, are now so common

in our cities, that, according to the most eminent writers on those diseases, every second man we meet is probably dyspeptic. From the close and vitiated air of cities, and the unwholesome occupations of many labourers and artisans, affections of the lungs have become much more frequent. Of the deaths in the metropolis, out of every 21,000, from 4,000 to 5,000 are said to die of consumption. It must here be observed, however, that, from superior skill, care, and attention, a greater proportion of weak and sickly children are reared than in a less civilised state of society.

Fevers of all kinds, though still occasionally prevalent, are much less so, and of a less fatal nature, than formerly. When they do occur they generally originate among the poorest of the community, and after unfavourable seasons and years of scarcity; and agues and intermittents are rarely met with except in the marshy districts.

It is unnecessary to appeal to Tables to show the great increase, of late years, in the average duration of human life; for no one will, we think, be inclined to deny, that although increased refinement has swelled the amount of chronic diseases, yet these, although sufficiently annoying, are, in the aggregate, less fatal to the human constitution than the acute maladies which formerly prevailed.

It is also unquestionable, that the rate of mortality is greater among the poor than the more prosperous classes of society. This may be accounted for from the superior comforts of the latter, and their exemption from severe labour; for, however essential due exercise is to the enjoyment of perfect health, it is certain that intense toil shortens existence. Few among the hard-working classes live beyond fifty or sixty years.

Another circumstance to be remarked is, the change in the relative healthiness of the seasons. Formerly more deaths occurred in autumn; the next season in unhealthiness was summer, and the smallest proportion of mortality took place in winter and spring; whereas at the present time the reverse of this is the case. Now, as the seasons have undergone no change, the peculiar unhealthiness of autumn and summer, is to be accounted for from the uncultivated, marshy state of the country, and the filthy condition of the large cities. In all partially cleared countries the same results are found, the most unhealthy seasons being the summer and autumn, from the occurrence of marsh miasma, and in all crowded and ill-regulated cities, the warm season is the most to be dreaded. In this country, again, the cold of the winter and spring months is what we have chiefly to contend against. A severe frosty winter has always been looked upon as the healthiest season we can have. Although such is generally the popular opinion, the reverse would appear from numerous observations to be the case. Both extreme cold and extreme heat are prejudicial to health; and moist weather, if mild, is preferable to very cold—nay, such is even healthy weather.

On a superficial view of the matter such opinions are somewhat startling. On a pure, dry, frosty day, the healthy and robust are vigorous, buoyant, and glad; they have animal energy sufficient to resist the cold. But the young and the aged, the feeble and the sickly, sink by hundreds under its chilling influence. In the winter months, by far the greatest proportion of deaths takes place among children; and it is then that apoplexy and diseases of the aged are most prevalent. Extreme heat is also fatal to the young and the aged; and on the whole, our healthiest seasons are found to be those which are the most temperate.

Sudden variations of temperature, too, are generally supposed to be unfavourable to health; but, although it is a maxim as old as Hippocrates, that neither heat nor cold are in themselves pernicious, and that the rapid transitions from one to another are alone to be dreaded; yet those seasons in which extreme degrees of temperature have taken place, and that to a remarkable extent, have not been found to be unusually sickly.

In conclusion, it may be worth our while to inquire, whether any new diseases have sprung up among us—whether Pandora's box has been replenished, or, whether it remains the same as when first opened on earth, to torment poor mortals. Many diseases, now well known and accurately described, were, it must be allowed, but obscurely or imperfectly hinted at by the ancient medical writers. Many diseases, too, are almost solely confined to particular countries or regions of the earth, and were of course unknown to old authors; but, still, there are sufficient allusions to a great proportion of the train of maladies incident to humanity, to make it appear pretty evident, that our present list of diseases has come down to us from the remotest ages. Owing to the particular circumstances of climate, locality, and many other adventitious causes, diseases sometimes prevail in a mild or an aggravated degree which very much modifies their character. Many, too, often appear, after long intervals, under various types; but, that the real nature of the maladies and their distinguishing peculiarities remain pretty much the same, we do not believe can be called in question.

The ills to which flesh is heir may appear aggravated in modern times; but this, in all probability, may arise from increased medical knowledge, which has taught men better to distinguish and classify them. It was not till the time of Boerhaave that the difference between rheumatism and gout was clearly discerned. The same might be said of many other maladies; and in this way the popular complaint, that diseases prevalent in the present day were never heard of among our fathers, may be well explained.

But, in considering the effects of increased civilization in improving the public health, the question naturally arises, how far this has been aided by improvements in medical science. We shall find that these have been considerable in modern times. The investigation of the structure and functions of the human body and the laws of animal life, but especially of the diseased action of the system, must, probably, ever be accompanied with extraordinary difficulties; yet great advances have nevertheless been made, and a much more accurate knowledge gradually diffused. The advance of chemical science, too, has wrought a wonderful revolution in the composition and prescription of remedies. The properties and actions of medicines are now much better known, and the list much simplified. The multifarious and heterogeneous farragoes of former days, in which some fifty or sixty various ingredients, of quite opposite qualities, were confounded in one potion, would not now be tolerated. Amid the general diffusion of knowledge, too, medical information is becoming much more common among all ranks; and an acquaintance with the structure and operations of the body—a knowledge certainly of the highest interest and the most practical importance—is ardently sought for.

Medical men are no longer held in superstitious awe, and, consequently, pedantry and mysticism have ceased to prevail. The days are gone by when Paracelsus alone possessed the knowledge of opium and mercury. There are now happily no secrets in the art, and the poorest student of Æsculapius may command the same means of information as the more highly favoured. The discoveries in anatomical knowledge have rendered the improvements in surgery even more striking than in relation to medicine. All tampering with nature is laid aside with the attempts to procure the philosopher's stone and the elixir of life. Nature, herself is no bad physician; and he who directs his art to aid her efforts, is best able to worship worthily at her shrine.

From this short sketch of diseases past and present, it would appear that increasing arts, increasing refinements, and what some are pleased to call luxuries, are not such very dreadful things after all. For ourselves, we are inclined to think that "nothing which is good can be bad;" and that, though we may now and then have a twinge of the gout,—that now and then a few inveterate topers or turtle-fed Aldermen may receive an apoplectic hint,—and that a portion of the community may be annoyed with blue devils, vapours, and the whole arrayed enemies of the dyspeptic hypochondriac,—yet, on the whole, that health and enjoyment are more universally diffused—that we have not, as formerly, a useful population cut off by sudden maladies, or disfigured by loathsome diseases; and although of late cholera has spread terror and lamentation over the land, yet even its visitations are at prolonged intervals. We bow, indeed, with all submission to the Hand by whom this dreadful scourge is sent. We try to feel that even it may be to our advantage; and we do not despair or even doubt, that, in His proper time, and in His own way, our ignorance of its nature may be permitted to be removed, and the disease conquered and overcome, even as others equally fatal.

And, again, let us compare our present homes with those of other days—of those of which Dryden tells us, where

> "The parlour window stuck with herbs around
> Of savory smell, and rushes strewed the ground."

Are not our regularly built, our airy and comfortable towns, where science, and wealth, and the enterprise of successive generations, have produced such an admirable system of order, convenience, and security, infinitely

preferable to the crowded, and polluted, and pestilent abodes of our ancestors? Are not our neat, and elegant, and warmly carpeted rooms superior to the clay floored, straw and rush littered apartments of Queen Elizabeth? And is not a highly cultivated, grain-waving country, a paradise compared to the gloomy forests and untilled marshy, and neglected soil of our forefathers? Have we not our gardens teeming with every variety of fruit and vegetable, where formerly only docks, and coleworts, and crab-apples grew, while in winter do not the supplies of art leave us little to regret the luxuries of summer? There is a cheering prospect, then, in the extending progress of knowledge towards the melioration of the human species; and among the other recommendations of advancing civilization, it is consolatory to perceive, that the sum of human suffering has been lessened,—that many of the most dreaded diseases which afflict mankind have either been wholly extirpated or very much mitigated,—that the nature and treatment of others are better understood,—that of all those who are born, a much greater proportion arrive at maturity,—and, consequently, that the average duration of human life has been prolonged.

SMOKE.

There is a tradition that, in a remote and mythical era, London was not "smoky London;" that there was a time when a Cockney did not consider the natural colour of his heaven to be a faded blue, the hue of his foliage to be a dirty green, nor wandering "blacks" to be the natural denizens of his atmosphere. Antiquarians, piercing through the dust of ages, have even declared that the Londoner of the Thirteenth Century preserved his lungs from carbonaceous contamination, by summarily punishing those who injured the purity of his air. Within the City walls he permitted no factory to pour forth its turbid streams, nor fiery furnace to darken all the land with smoke. Even so late as the reign of Edward the Third, it is said that the extreme penalty of the law was inflicted on a rash manufacturer, who carried on his sooty trade within the interdicted space.

Since those days, manufacturers have gone ahead, and have used our atmosphere very much as if it belonged to them alone, and was not the common property of us all. "As free as the air we breathe" is a proverb which any time these hundred years has been falsified by the fact. Everywhere in this country we breathe an air which is anything but free; for it is loaded with foreign particles, and its native oxygen and nitrogen are cruelly compressed or thrust aside by the vile carbonaceous canopy under which our unscrupulous merchant-princes compel us to dwell. And the worst of it is, that we have become so accustomed to this usurpation, that all our lives we go on swallowing coal, blackening our lungs, spoiling our complexions, and impairing the whiteness of our linen, with the submission of men without hope, and with the resignation of those who suffer from an irremediable evil. Nay, in the very abjectness of slavery, we defend our oppressors; we cannot see an immense chimney pouring out its sooty particles, without taking it as the emblem of commercial activity; we compare a steamer enveloped in its dirty cloud to a volcano whose overhanging mists testify to the mighty forces which hurled them from below; we gaze at night, from the Surrey hills, on the lights of London, reflected from the enveloping smoke, with a profound sense of the life and vigour which is going on beneath that *opaque* covering. And thus, because we are a great manufacturing people, and because we cannot disconnect the ideas of factories and smoke, we see, without an attempt to prevent it, the once verdant hills and dales of Staffordshire gradually denuded of verdure like the sand-mounds of the desert, and the great cities of Yorkshire and Lancashire daily becoming more like the cities of miners, who live in the bowels of the earth, than to the dwellings of men who are supposed to have an unintercepted and blue sky above them.

And surely here is a great mistake. Manufacturing greatness is not measured by soot. If we could burn our coal properly we should at once free ourselves from this intolerable nuisance, and at the same time actually benefit the manufacturer. If we could insure *complete* combustion we should have no smoke. We should still, of course, have carbonic acid, but we should have no small particles of unconsumed carbon escaping into the air. The existence of smoke gives evidence of waste of fuel. Let those who are interested in this subject read the Report of Sir Henry De La Beche and Dr. Playfair. The difficulty is to burn all the charcoal. We do not deny that there are practical obstacles to this; still it might be done and to a much greater extent than is accomplished under the present careless and irresponsible mode of proceeding. Every manufacturer should be compelled to do it; and the compulsion would even be beneficial to himself. In Sheffield, where an Inspector kept the manufactories in order, the smoke nuisance was for a time much diminished, and why should we not have in London the same regulation.

We are happy to see that a Bill has been introduced into Parliament on this subject, and has gone into Committee. We have seen great deeds accomplished of late years in the Lower House: the Corn-laws have been abolished, the Navigation-laws abrogated. If the Legislators will do away with our smoke, they will have accomplished another improvement deserving of applause. The Legislature seems, however, to feel that there is an obscurity about smoke; and the short debate we have at present had, has done full justice to the opacity of the subject. Honourable Members had some difficulty in defining the evil upon which they were about to legislate, although to assist them at the very moment the question was under debate, a sudden eruption of smoke, introduced through the ventilating apparatus in the House of Commons, was an apt illustration of the expediency of doing something. What is "opaque smoke"? asked Mr. *Bright*. "Smoke which you cannot see through," was the logical answer of Mr. Mackinnon, and at the moment the black cloud rising between the two senators, confirmed the unanswerable truth of the definition.

We shall allude at some future time to the evils inflicted on the human frame by this constant inhalation of smoke. Although Science has not yet absolutely traced the injuries which result from it, we cannot but suppose that injury must exist. When inhaled in very large quantities, we know that serious mischief does ensue. True, Nature in her conservative power, ever endeavours to save us from all pernicious consequences. She stores up the fine particles of carbon in the intercellular pulmonary passages, away, if possible from the fine membranes on which the vascular network is spread out. She, perhaps, even absorbs gradually the carbon into the blood, and then carries it off in the respiratory act. But yet we know that this foreign introduction can hardly take place without some impairment of healthy respiration, and some corresponding depression of vital power. As Medical men, we need not demand that the exact influence of smoke inhalation shall be proved; it is enough for us that it is unnatural, and, therefore, must be hurtful. On medical grounds, we desire, then, that the Legislature deliberate on the subject.

THE MEDICAL CORPORATIONS OF EDINBURGH AND GLASGOW.

According to our Edinburgh Correspondent, a friendly meeting between a party of Medical men of that City and some of their brethren in Glasgow, was lately the topic of Edinburgh discourse. But now, a source of dissension between the Medical Corporations of the two cities has transpired. It appears, that, to facilitate the arrangement of the provisions regarding Scotland in the expected Medical Reform Bill, conferences took place last summer between delegates appointed, on the one hand, by the two Edinburgh Royal Colleges; and, on the other, by the Glasgow Faculty of Physicians and Surgeons. The twofold basis of these negotiations was the surrender, by the Glasgow Faculty, of the privilege of granting Diplomas, and the admission of its members into one or other of the Edinburgh Colleges, in the event of these becoming the Royal Colleges of Scotland. Certain points were agreed on,—other points were referred to arbitration; but no decision on the disputed matters was given, owing to the Bill having been abandoned. The subject was taken up again this year, and the Glasgow Faculty consented to refer anew to arbitration all the points in dispute, with the exception of one, which they resolved to hold by in Parliament; namely, that a Board of Glasgow medical men should retain the power of examining Glasgow students for the new diploma to be issued, as was proposed, in the joint name of the Royal Colleges of Physicians and Surgeons of Scotland. This the delegates of the Edinburgh Colleges resisted, on the ground, that it would be equivalent to continuing the Glasgow Faculty as a licensing body with a new status to their diploma; contending, further, as the members of the Glasgow Faculty, though no longer to constitute a Medical Corporation, were to be entitled to act as assessors in the examinations for the degrees of Doctor and Bachelor of Medicine in the University of Glasgow; and as sufficient funds were to be provided to keep up the Faculty as a Literary Institution, that their opponents were asking more than their present position gave them any claim to obtain.

So long as these debates were confined to the delegates, the Profession at large, in the two cities, knew little of what was going on; but, in the course of the past month, the Glasgow delegates issued a Circular, appealing from the delegates to the Fellows, individually, of the two Edinburgh Colleges; this produced a reply from the Edinburgh delegates, explaining the whole question to their constituents, and this again a counter-statement from the Glasgow delegates,—so that the whole matter, though not actually published, being in print and extensively circulated, is now quite *publici juris.* The Glasgow Manifestoes do not urge so strongly the argument that, in the event of a new Act, they are promised less than an equivalent for what they hold at present, as that the Glasgow Faculty, being an old chartered body in a great city, and, therefore, as much entitled as the two Edinburgh Colleges to become a Royal College of Scotland, is unjustly denied a share in that extension of privileges which the two Colleges of the metropolis of Scotland, on becoming national, are to obtain. The main point at issue, then, is the present status of the Glasgow Faculty of Physicians and Surgeons. The Edinburgh arguments proceed on the principle of simple compensation, and claim credit for offering a full equivalent for the value of the surrender. The Glasgow Faculty think their position entitles them to a continued existence as a local licensing body, with a national name to their diploma.

It will be for Parliament to determine, if the question ever come to that stage, whether the Glasgow Faculty have reason in their claim. The mere argument of right from their charter will hardly suffice in this charter-breaking age; but Parliament will not refuse to listen to a plea drawn from the repute of the Glasgow body among the Medical Institutions of the Kingdom, if derived from the celebrity of its members in the annals of Medicine, from the efforts it has made for the improvement of Medical education, from the credit of its Examinations with the Public Boards, from the esteem in which its diploma is held in the country at large, as a qualification for practice, and for the liberality with which it has been accustomed to exercise its corporate privileges.

UNIVERSITY COLLEGE AND ITS RECENT APPOINTMENTS.

We some time since expressed the interest we felt in the appointments that must during the summer be made by the Council of University College to the Chairs of Medicine, Clinical Medicine, Pathological Anatomy, Materia Medica, and Medical Jurisprudence. To choose five new Professors, able and willing to undertake the responsible posts, was a duty involving a risk of no trifling nature to the future well-being of the Institution. Of the wisdom displayed in the choice of a successor to Dr. Williams, we have already stated our opinion, and we believe that opinion is the one universally entertained by the Profession. An equally judicious appointment has been made to the Chair of Clinical Medicine. Dr. E. A. Parkes was some years since one of the most distinguished pupils of University College. He gained high honours at the University of London, and received from that Institution a recommendation for an appointment to an assistant surgeonship in the army. He served some years in India, and soon after his return to England, in 1845, was elected assistant-physician to University College Hospital. The Works of Dr. Parkes on Cholera, Dysentery, &c., have earned for him a high and well-merited reputation, and we believe no appointment could have been made more agreeable to the pupils of the College, or more consonant with the wishes of those who desire the success of the Institution.

We trust the other Chairs will be filled as judiciously as have been those of Medicine and Clinical Medicine. If they be, the College will have derived new life and vigour from losses which at first threatened it with serious injury.

LORD ASHLEY AND THE BOARD OF HEALTH.

We see Lord Ashley has asked leave to introduce two new Bills into Parliament, to facilitate the operations of the Central Board of Health. We wish he could make an effective Act to introduce a few grains of Medical logic into the heads of his fellow-members of the Board. We feel the want of one or two active Medical men in Parliament, endowed with plain sense, who could expose to the country the downright nonsense which, from the late specimen, we fear it is condemned to swallow for some time to come in nauseous doses, under the prescription of the Board.

THE FLEMISH TWINS.

The case narrated and illustrated in another part of our Journal, offers the greatest similarity to that of the Siamese twins, which was brought before the public some years ago; the condition as regards the sternum and ensiform cartilages and umbilicus, being, if we do not mistake, identical; only traction seems to have rendered the union a little more pliant.

There is very little doubt, that in this, as in most of these cases, the two livers are united by their anterior part, a complication which would of course go yet further to negative the idea of an operation. The Siamese twins, too, could never be brought to see the advantage of separation, at least not while in Europe. But they subsequently married.

It is very difficult to offer any remarks upon the nature of these junctions. The curious in these matters may consult the great works of St. Hilaire and Otto, on misdevelopments in general, or the admirable monograph of Vrolik on double monsters in particular.

The form before us is by far the most common of all. Some twenty or thirty cases are, we believe, known and recorded.

It is somewhat singular that the majority seem to be female twins: at least three-fourths of those recorded by Otto were female. So far as we know, the sex is invariably the same in both.

The sympathies of these double monsters are remarkable. We do not merely allude to the coincidence of feelings and habits often seen in ordinary twins, which is, perhaps, explicable enough as an exaggeration of that identity of physical and mental conformation and circumstances which often obtains in children of the same parents. But we cannot help noticing that the *humoral* mixture which must result from the vascular anastomosis of the twin monster is obviously the cause of their liability to, or co-affection with, the same blood disorders; while the distinctness of their animal functions is mainly due to that of the nervous system.

The higher philosophical import of these misdevelopments is as yet little appreciated. Vrolik's theory is, that they are not fusions of two into one, but rather fissions of one into two,—not attempts at unity by two, but attempts at duplicity by one—ovum. This view implies a greater power of the germ: or, in other words, just as Professor Owen supposes a higher germ-power, perlongated as to time, to give rise to parthenogenesis; so a higher germ-power, exerted at once, produces these developments of stray limbs, parasitic fœtus, and, finally, of double monsters.

If we might hazard any rash conjectures on such a very intricate subject, we should like to point out that the placenta is almost, but not invariably, simple, and so, also, is the umbilical cord; and that similarly there is generally something abnormal about the vessels of this part, not merely in the bifurcating umbilical vein, but in the want of minute division of the hypogastric and umbilical arteries of one of the twins. Often the latter difference appears to be associated with (to regulate?) a deficient development of that one.

Now, if we apply the theory of Vrolik, it would appear from hence that the placenta and its immediate off-shoots are less disposed to share in this excess of germ-power than any other part, and that thus the parts nearest to them become implicated in a similar unity.

And if we continue our speculations, and boldly regard ordinary twins as formed on the same law—or as a fission (a) of one ovum into two, we may still notice, in the frequent *oneness* of the placenta, a repetition of the same statement. But why, on this theory, should twins be so frequent, and monsters so rare? Why should there be, in the mass of instances, either a sufficient energy to form *one*, or, overpassing this, to form *two* perfect fœtuses? We can offer no cause but a *final* one, which, in this instance, would be no cause at all.

THE ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

The Session of the Royal Medical and Chirurgical Society has been brought to a close, and we publish this day the papers read at the last meeting. Among the Medical Societies of this metropolis, there is not one holding so distinguished a position as the Royal Medical and Chirurgical, and the abstracts of the papers read at the various meetings, published in our columns, are always perused by the Medical Profession with much interest. We have, in consequence, regularly furnished to our readers those abstracts, with the discussions which took

(a) The word is here employed, not to signify the *fact*, but rather the *tendency*, since the ovum, at this date of early development, must be regarded as a multitude of homogeneous and fissiparous cells.

place upon them. In reviewing the transactions of this learned body during the past Session, we have no hesitation in saying that they are indicative of increasing prosperity. Though there has been some slight misunderstanding on points connected with the administration of the affairs of the Society, we are glad that it is not such as to peril its future advancement, and a goodly number of new members has been enrolled.

The papers which have occupied the attention of the Fellows, at their various meetings, have, upon the whole, exhibited a highly scientific and practical character, and will be worthy of a place in their published Transactions.

To the young medical man this Society offers especial advantages. In addition to affording him intercourse with some of our first Physicians and Surgeons, he has the privilege of access to a splendid library. Here he may consult Authors whose productions, from their high price or rarity, he cannot purchase; while he also is enabled to read most of the professional works which are constantly issuing from the Press. With these attractions, the Society has nothing to fear from any rival; and with such meetings as those which took place during the last session its popularity must increase.

THE OPERATIVE SURGERY OF JOHANN FRIEDRICH DIEFFENBACH.

EDITED BY
J. STEVENSON BUSHNAN, M.D.,
Fellow of the Royal College of Physicians of Edinburgh, &c., &c., &c.

EDITOR'S PREFACE.

It is with infinite pleasure that I have undertaken to edit, and to offer in an English dress to the readers of the *Medical Times*, the great work on Operative Surgery of the celebrated Professor of Berlin, Johann Friedrich Dieffenbach. To me it is a labour of love, and that rendered still more pleasing from having been suggested to me by my lamented friend, and executed in fulfilment of a promise now, alas! become sacred:—

"τους αγαθους και θανοντας ευεργετειν δει."

These, however, are private reasons, depending upon personal feelings and grateful recollections:—

"Multis ille quidem flebilis occidit,
Nulli flebilior quam *mihi*."

There are public and higher grounds for presenting this work to the Profession. To speak of the renown and celebrity of Dieffenbach is superfluous. Wherever surgical science has reared its head, these are known and fully appreciated. His work, an analysis of which I propose to offer to the English reader, gives the result of the experience of the greatest Surgeon the world ever knew,—for in him were united the practical knowledge of Colleges and the inventive genius, I may almost venture to say, of the whole surgical world. Such a work cannot but be of the highest interest to every member of the Profession. The book is essentially his own. He borrowed from no man:—of what writer on surgery can the same be said? In this respect it stands in remarkable opposition to the work of Chelius of Heidelberg—excellent, no doubt—but which is a mere compilation, fashioned and well arranged, from many sources, and considered in Germany as a useful text-book for the student; while, by careful collation in the hands of its enlightened English editor, Mr. South, it has received no inconsiderable improvement—indeed to him it owes its greatest excellence. Dieffenbach's work, on the contrary, moulded in another shape, assumes a higher rank. It is for the practical surgeon. It is no compilation. It is drawn from the author's own resources. It relates the conceptions of the man, and develops them in action. To these I shall strictly confine myself, passing lightly and analytically over the generally accredited facts of the science, and insisting more especially upon those points peculiar and proper to the author.

I trust to be able to do justice to the great original, and to offer a clear and comprehensive exposition of his views and opinions to the readers of the *Medical Times*. But to do so, all slavish adherence to the *litera scripta* must be thrown aside, and although, in translated passages, the critic may sometimes fail to recognize the *ipsissima verba* of the author, he may rely that the sense and meaning has been religiously preserved. J. S. B.

AUTHOR'S PREFACE.

My immediate object in the publication of this work is to impart what useful surgical knowledge I possess; and I write chiefly for those whose experience has not been great.

August Gottlieb Richter tells us in the Preface to his Treatise on Hernia:—

"I wish to produce a work which shall embrace, in a condensed, but clear and perspicuous form, the riches of surgical science—a work void of learned gloss, and only destined for the practical surgeon—in fact, a work simple as Nature herself. My object is not to write learnedly, but clearly and instructively. I do not write for the learned world, but for the practical surgeon; and I desire that there shall not be found a page in my book from which something useful may not be gleaned."

May mine prove such a work!

Its composition has not been tedious and irksome to me. It has be n an agreeable task, and as such I wish the public to receive it. It is written, too, without prejudice; and this, I think, all, capable of judgment, will admit, even although they be not practical surgeons. The reader will find that this work is founded upon what actually occurs in practice; and that I have had great experience it is hardly necessary to mention. I have stated that which I have really seen; and I have viewed nothing through the "dim obscure" of strange or coloured glasses. Neither have I, in the decline of a long and chequered life, recalled the recollections of my prime, and given them to the world. I write in the vigour of my manhood, and record the events as they occurred in my practice of yesterday, and of to-day, and as they will to-morrow.

But from this it must not be supposed that I trust exclusively to my own resources; that I have not availed myself of the researches of others, or even have witnessed every truth I have recorded. On the contrary, though I have added much to the stores of surgical knowledge, I have learned much from the experiences of others. That I do not quote authorities for generally admitted facts, hardly requires an apology; and the vast amount of valuable information that exists, particularly on surgical therapeutics, using that term in contradistinction to operative surgery, which is more immediately the object of this Work, rendered it difficult to make an impartial selection. It has, however, been my endeavour to throw aside the least important, and to adopt the best.

After all, perhaps, my Work may not be popular. Some may call it unscientific, because the most ordinary practitioner can understand it. Others may say it is incomplete, because it does not seem to me necessary to republish useless matter. To please all classes, however, would be as unsuitable for the writer as for the reader. But should there be much to censure, I still trust more will be found worthy of praise—at any rate, much that I have written has already received the sanction of the most able and accomplished members of the Profession—of those whose opinions I value most. I have, therefore, little to fear from others. I have expressed my opinions boldly and fearlessly, because I have deemed it expedient. Besides which, in science, there exists no middle course between the "yes" and "no."

For the sake of younger readers, I have endeavoured to make my sketches as graphic as possible. Although drawn in glowing colours, they are accurate portraits; and since they are not overloaded with extraneous and meretricious ornament, they will at once be recognised, and not easily forgotten. My operations, too, are described in the simplest manner; and I have not thought it necessary to inform the reader that bleeding must be stopped, water and sponges used, and arteries secured; or to enter into any such trivial minutiæ.

In conclusion let me acknowledge my obligations to my friends Messieurs Angelstein, Holthoff, Reiche, Völker, Ribbentrop, and Hildebrandt, for the assistance they have rendered, both in my public and private practice, and to whose indefatigable exertions so many patients are so deeply indebted.

INTRODUCTION.

The department of medical science which excites the greatest degree of enthusiasm in the mind of its follower is, undoubtedly, operative surgery: and well, indeed, that it is so. Great must be the enthusiasm, and greater still the love for his profession that sustains the Surgeon, and enables him, without a shudder, to plunge his knife into the human body; to guide it calmly and deliberately as deeper, and deeper still, he cuts; to receive, unshrinking, the warm and reeking life-blood upon his person; to hear, unmoved and with unquivering heart, the agonising cry of the mutilated patient, and this without a moment's loss of self-possession, without ceasing either to feel or to think. Operative surgery is a bloody contest with disease—a struggle with death for life. The victory is not to be won by rashness nor by insensibility. It is obtained by skill, by science, by self-possession, and inventive genius; and without the strongest and yet the most unpresumptuous conviction of capacity, without an enthusiasm that overcomes every other emotion of the mind, let no one devote himself to its pursuits; he who does so must ever remain a novice, vainly knocking at portals he can never enter. However deeply he may have studied the healing art, however well he may be acquainted with all that surgery has recorded, and however versed in all the operations that have been performed or proposed, without other qualifications, no man can become a skilful surgeon—he must ever remain a journeyman in his craft. The distinctive marks of a perfect surgeon are, that his operations should be instinctive; that he should be a man of individual resources, and know and be able to perform that which is not written; that his creative genius should never forsake him; that it should avail him on every emergency, and never be at fault; that he should be able to invent, not only a new bandage or a new instrument, but that he should, under the most sudden and trying circumstances, possess the power to adopt means to an end, and to gain the victory—what though it be a bloody one—even without a council of war. The painter having learned the fundamental rules of art, the mixing and application of colours, the copying of models and the harmony of light and shade, throws aside the designs of others, he relies upon his own imagination, and paints his thoughts. The scholar may learn to make verses which scan correctly, and read with sufficient euphony; but, unless born with the "divinus afflatus," and feeling the inspiration of which Cicero wrote, he will never be a poet; and so the routine surgeon, who only knows to operate from books and from example, who has become a mere copyist and slavish mannerist, will find himself sadly at a loss, when called upon by circumstances to do that of which he has neither read nor seen performed. Men who can do this, are those alone to whom the term of Operative Surgeons should be applied. Though few in number, they have existed in all countries; and their surgical talents are to be estimated, not by the numerical amount and the magnitude of the operations they have accomplished, but by the

manner in which they have described them. The skilful surgeon is distinguished by the intelligibility of his ideas, and the simplicity with which he developes them; and it is impossible to have performed an operation well, unless the surgeon can also describe its steps with clearness and perspicuity. The most able surgeons have always been remarkable for lucid perspicuity of style. Percivall Pott in England, and Samuel Gottlieb Richter in Germany, afford examples in point. If all able surgeons have not written so well as these, their works are nevertheless characterized by clearness of idea and simplicity of expression; while they have avoided following the example of their more medical contemporaries, who, infected with the chimerical and philosophical doctrines of the day, borrow wisdom from each other, and, like the earlier writers, parade the doctrines of the schools. The same is said by Kurt Sprengel, in his history of surgical operations; and, although I would strongly recommend all physicians to study, at least, the Preface of that work, I will not here repeat his remarks, lest I should gratuitously offend and insult men exclusively devoted to the science of medicine. The history of Surgery teaches us that, from its birth, from the moment when the first splinter was drawn from the skin, even to the present day, it has always been progressing. During the middle ages, it was somewhat in abeyance, and, although Sprengel asserts that it has, of late, been retarded in its progress by the jealousy of mere physicians, I will not acknowledge such a disgrace to Surgery, nor such littleness of mind in its followers. It can never yield to the pressure of medicine; for its acts speak for themselves, and must overcome all opposition.

To practise surgery with success requires not only a facility in operating, but great mechanical genius. Different, indeed, are the qualifications the world thinks necessary to a good surgeon. To some, a man of herculean strength and strong athletic frame seems best suited to fracture bones and force joints into their proper places; others seek aptitude in the eyes whose piercing acuteness they suppose to discover what to others is concealed; while most persons regard the fingers as the seat of the surgical soul, and imagine that the test of competency consists in a sort of legerdemain, by which a limb is removed in a given number of seconds, and the knife handled with so much celerity that its movements can be scarcely followed. Physicians themselves are among this class—they place the talent of the surgeon in his fingers, appropriating to themselves the higher faculties of the mind; and yet the success of an operation depends chiefly on the indications laid down for its performance, the manner in which it is performed, and the subsequent treatment. Cruelty and hardness of heart have of late been considered essential to a good surgeon; but surely there is a great difference between cruelty and firmness, and, in so painful a procedure as a surgical operation, compassion and forbearance cannot be wanting.

(To be continued.)

MEMOIR OF DR. A. T. THOMSON, LATE PROFESSOR OF MATERIA MEDICA AND OF MEDICAL JURISPRUDENCE IN UNIVERSITY COLLEGE, LONDON.

By an OLD STUDENT OF THE COLLEGE.

The subject of the present memoir, the late esteemed Professor of Materia Medica in University College, was born at Edinburgh in January, 1778, and, consequently, at the time of his death, was in his seventy-second year. His father was a Scotchman, who had emigrated to America, and held the lucrative post of Commissioner of Customs in the town of Savannah, in Georgia. He had arrived on a temporary visit to his native country immediately before Dr. Thomson's birth, but shortly after this event he returned to America, and remained there till the termination of the War of Independence. Dr. Thomson's father, in addition to the Commissionership of Customs, held the appointment of Postmaster-General of the province of Georgia, and was also a member of the Government Council. Like many of the American Loyalists he threw up his appointments when the peace was proclaimed, and returning to England, received a pension from Government, and retired to Edinburgh. Dr. Thomson was educated in the High School, and subsequently in the College, of Edinburgh. Among his school and college friends were Leonard and Francis Horner, Henry Cockburn, afterwards a distinguished orator of the Scottish bar, and now one of the Lords of Session, and several others whose names have since attained a wide celebrity. At the time of Dr. Thomson's attendance at Edinburgh the fame of this great medical school was at its height; the names of its teachers, Monro Secundus, Gregory, Black, &c., were known all over the civilized world. Dr. Thomson attended the last course of lectures ever delivered by Dr. Black. During his attendance at the College, Dr. Thomson became a member of the Speculative Society, and mingled in the celebrated debates which then exercised the talents of many who were afterwards destined to play no inconsiderable part on a much wider stage. Here it was that Dr. Thomson formed the acquaintance of Lord Brougham, and laid the foundation of a friendship which continued during his whole life. Dr. Thomson graduated at Edinburgh; and having the misfortune to lose his father about this time, and finding that he was left entirely dependent on his own exertions, he determined to commence practice in London, which he accordingly did, after joining the College of Surgeons in London, as a General Practitioner in Sloane-street. He rapidly acquired a large practice, and in 1801 was married to Miss Maxwell, of Dumfries.

In 1810 he commenced a course of lectures on Medical Botany, which was for many years the only course of the kind in London. It was very popular, and many of the most eminent men of the day became his pupils. Shortly afterwards he published his "Conspectus of the Pharmacopeia." This little book, the most popular one of its class, was sold to Underwood, the publisher, for 20*l*. Some idea of its astonishing success may be learnt from the fact, that after passing through five editions, the copyright was bought by Messrs. Longman and Co. for 600*l*. It has since passed through many more editions, and has brought immense profit to its proprietors, though very little to its author, who merely received 20*l*. or 30*l*. for revising each fresh edition. In 1811 Dr. Thomson published the "London Dispensatory," a work of such merit as at once to command a very extensive circulation, and to place the name of its writer among the first class of medical authors. It has passed through eleven editions, the last being published in 1844, and still preserves its reputation of being the best book on the subject. It is a work of great erudition, containing an immense amount of information, admirably put together in an easy and lucid way, and being illustrated with a great number of original experiments and observations. In the Preface to the first edition the Author apologises for its imperfections on the ground that it had not been written amidst the appliances of learned leisure, and the ease of an undisturbed study; but had been composed among the harassing cares and distractions of a most extensive practice. Had such an apology been needed, it might be said that this was most literally the fact, as it was usual for Dr. Thomson to rise at five o'clock in the morning, write for three hours, then spend the whole day in visiting his patients, return to a late dinner, and then work till two o'clock in the morning. Indeed, he never allowed himself more than three or four hours sleep. In 1814, Dr. Thomson became with Dr. Burrows and Mr. Royston one of the editors of the "Medical Repository." This Journal, which speedily commanded a wide circulation, and exercised great influence with the Profession, was established both for the purpose of promoting medical science, and with the view of becoming the organ of the associated Surgeon Apothecaries, who were then agitating for the medical reform which afterwards took the shape of the Apothecaries' Act. Dr. Thomson was one of the most energetic Reformers, and embraced the cause of the general practitioners with his accustomed ardour. It was, in great measure, owing to his energy and to the skill with which he and Dr. Burrows advocated the claims of the Apothecaries, that the first instalment of medical reform was obtained for the Profession. Although, at this time, Dr. Thomson was overwhelmed with a great private practice, he wrote largely for the "Repository." In the copy which he kept, and which, through the kindness of his family, we have been permitted to inspect, the names of the writers are attached to each article. To those who are curious in such matters, we may now safely permit a glance within the editorial sanctum. The first original article in the Journal, viz., "Two Cases of Hydrocephalus Acutus" is by Dr. Thomson; and the symptoms and *post-mortem* appearances are detailed with great minuteness. In the same Number is a very able, and rather sharp review of the fourth volume of the "Transactions of the College of Physicians," also from his pen. In the second Number, "the Reviews of the Progress of Chemistry," "Materia Medica," and "Botany" on the Continent, are by him, and, in the subsequent Numbers, he wrote the greater part of the Reviews, and of the "Analyses of Foreign Medical Science and Literature. Those Analyses were subsequently lengthened into "Retrospects of Medical Science," which are perfect models of what such things ought to be, and show to the greatest advantage the singular talent which their writer had of collecting from innumerable sources every important and novel fact. It is astonishing, how Dr. Thomson, even with his power of work, could have found time, at this period, to fulfil his numerous engagements. He was doing a private practice of about 3,000*l*. per annum; he was an active member of the Apothecaries' Committee, (and several speeches reported in the first volume of the "Repository," testify to his exact appreciation of the question of Medical Reform,) he was delivering Lectures on Botany, and performing an amount of literary labour for the "Repository," which, by itself, would have engrossed the whole time of many men. Shortly after this time, the first case of poisoning by oxalic acid in England was published in the "Repository," by Mr. Royston, and Dr. Thomson immediately entered on an investigation into the chemical and medicinal properties of this acid, which ended in the publication of some Toxicological papers, to which succeeding writers have continually referred. He discovered also the best antidote to poisoning by oxalic acid, and, in fact, went over the ground which was afterwards trodden in the same way by Orfila. In 1815 and 1816 Dr. Thomson was engaged in numerous inquiries into the microscopic structure of plants, many of which are of great interest, and are contained in his work on Botany, published two or three years subsequently. In 1818 the *Medical Repository* was sold to Underwood. Dr. Thomson continued, however, to be a large contributor to it, and the Retrospect of the Progress of Medicine which opens the volume for that year, and occupies more than sixty pages, was written by him.

In 1820, having for some time been a widower, he married a second time.

In 1826, Dr. Thomson removed from Sloane-street, to Hinde street, Manchester-square, and became a member of the College of Physicians.

In 1828, University College, or, as it was then called, the London University, opened its theatres to the public, and Dr. Thomson was elected the Professor of Materia Medica and Therapeutics, a chair which he held till his death. In the following

year he published an edition of Bateman on Cutaneous Diseases, with Plates. In 1832, on the death of Dr. Gordon Smith, he was appointed Professor of Medical Jurisprudence in University College, in conjunction with Mr. Amos, but shortly afterwards, when Mr. Amos accepted a Judgeship in India, Dr. Thomson became sole Professor, and continued so till his death. During this part of his life, from 1829 to 1849, he continued to manifest the same indefatigable industry as during his career as a General Practitioner. His private practice was considerable; he was Physician to the Dispensary attached to University College, and, subsequently, to University College Hospital; he delivered complete courses of Lectures on Materia Medica and Medical Jurisprudence, and gave weekly Clinical Lectures; he published a great number of scattered papers in the *Lancet, Medical Gazette, Monthly Journal of Medical Science*, and *Medico-Chirurgical Transactions*, and he contributed numerous Articles to the "Cyclopædia of Practical Medicine." He also published Lectures on Medical Jurisprudence, and the "Elements of Materia Medica," a text-book intended for the use of his class, which has passed through three editions. He wrote a very useful work on the Domestic Management of the sick-room, which had a very large sale, a short treatise on Botany for the Society for the Diffusion of Useful Knowledge, and published two or three Fasciculi of Plates on Skin Diseases.

In 1841 he commenced a course of Lectures on Botany for the Pharmaceutical Society, and continued them until his last illness. About ten years ago he was elected a Fellow of the College of Physicians, a distinction which, considering his reputation and his character, might have been sooner bestowed upon him. In addition to his extensive professional avocations, Dr. Thomson found time for various literary pursuits; he wrote many papers for the periodicals of the day, such as Colburn's *Monthly Magazine*, the *Foreign Quarterly Review*, the *Literary Gazette*; he translated Salvert's work on Magic, and edited, with copious notes, the "Seasons" of Thomson. These non-professional pursuits were carried on in what he called his leisure time, which consisted merely of the three or four hours he snatched from sleep, after fourteen or sixteen hours unremitting application to professional duties. During the last two years of his life he had been engaged in throwing his notes together for the purpose of writing a work on Diseases affecting the Skin, a task for which his great experience in these affections qualified him more highly than any other practitioner of his day.

In the summer of 1848 both his mind and body seemed to be as strong and active as ever. He was accustomed to rise at six in the morning, walk up to the Botanical Gardens in the Regent's Park, deliver from seven to eight his Lecture to the students of the Pharmaceutical Society, then return and see patients till half-past twelve. At one o'clock he went to his hospital, and at three lectured on medical jurisprudence. Once a week, also, he gave a clinical lecture, and on these days, therefore, was actually engaged in lecturing for three hours. After his lecture on jurisprudence he made his visits till a late hour in the evening, returned to dinner, and after dinner commenced preparing his lectures for the following day, writing reviews, and medical papers of all kinds, arranging his book on skin diseases, or collecting materials for the next edition of his "Dispensatory," which was his favourite and most profitable work. After many hours' labour he would lay aside his professional work, and take up some of his lighter pursuits, and then, at two or three in the morning, retire to bed for three or four hours. He found time, somehow or other, to read all the medical publications, both periodical and otherwise, and studied many of them as attentively as if he had been a student of 20 years of age. At the time of his illness he had been very carefully reading Feuchtersleben's Medical Psychology, and had half completed a long review of it, intended for one of the leading medical journals.

In spite of this intense occupation, at the commencement of the session in October, 1848, he had never seemed in better health, or more active in mind. In January, 1849, however, he caught cold, and had a very severe attack of bronchitis; after two or three weeks' illness he went into the country, and soon regaining his strength, insisted, contrary to the advice of his friends, on returning to his work. He entered upon his duties as usual, but, probably from the exposure which a professional man cannot wholly avoid, again suffered a return of bronchitis, with which a little pneumonia was now combined. This was, however, soon subdued, and he left town for a few days to recruit. He came back strong and active, although the cough had not entirely disappeared, and recommenced his lectures and hospital practice. Immediately before the termination of the winter session, he was accidentally exposed to cold, and felt chilled and indisposed; instead of returning home he went his round of professional engagements, but while engaged in writing a prescription at the house of a patient, was attacked with a fainting fit. He soon recovered, finished his prescription, and returned home. The next day he felt himself too unwell to go out, and when visited by his professional friends, it was found that extensive pneumonia of the right lung had set in. This was apparently soon got under, and at one time he seemed rapidly recovering, and was able to leave his bed for six and eight hours a-day. Without assignable cause, however, the disease again partially returned, pleurisy to a considerable extent complicated the case, and after lingering several weeks in a state of great debility and exhaustion, he gradually sank, and died on the 3rd of July. The mind remained perfectly clear and active till within a few minutes of death; till within a few days he had continued the dictation of his work on skin diseases, and had consulted authorities on the subject. He bore his illness with extreme patience, and contemplated its inevitable termination with the fortitude of an honest man and the calmness of a Christian.

We cannot conclude this brief notice of an excellent Physician and most exemplary man, without a few remarks on the character of his intellectual powers, and on the claims which his memory has on the gratitude of the Profession. And we may remark, in the first place, that this spectacle of man engaged for so many years in the engrossing occupations of general practice, and yet finding time not only to keep up his own knowledge of his profession, but to add materially to the general stock, is an example which every man would do well to copy. Let those who regard the General Practitioner as one of an inferior class, or as one who, in the multiplicity of his engagements, is obliged to abandon all independent observation, confess their error, observing how Dr. Thomson, while engaged in the largest practice in his own part of London, appeared as the only instructor in a very important branch of medical study,—published works which, even after nearly forty years, remain unexcelled,—agitated unceasingly to obtain from the Medical Corporations consideration and justice for his professional brethren,—and, in fact, realized, in his own person, the beau-ideal of an accomplished professional man, at once literary and practical, a profound scholar, and an excellent practitioner,—doing his duty to those whose lives, under Providence, were committed to his charge, and, at the same time, working honestly and disinterestedly to advance the art which he practised, and to promote the good of those who practised it with him. But those who would judge Dr. Thomson only from his published works, would hardly do him justice. In common with most men who write largely in Medical Periodicals, he exerted a great, though unseen influence on professional opinion. Many who have read only his "Dispensatory," have been too ready to regard him in the light of a compiler. In order to form an estimate of his critical faculty, or of the real extent of his knowledge of Medicine, it is necessary to consider the numerous anonymous Reviews, Retrospects, and Reports which he published from 1814 to 1820. Even his family are acquainted with only a few of these, and with those merely by accident; but those who will take up the ten first volumes of the "Medical Repository," will find, that the ability with which this Journal was conducted, and the scientific character of its contents, which were in great measure attributable to the subject of this memoir, would do honour to any Editors or Writers of the present day. Dr. Thomson, also, was one of those who, more than forty years ago, foretold the vast influence which microscopic investigations and organic chemistry would have upon Medicine. He had even made microscopic examinations of morbid products, which must have led him, had his occupations permitted him to continue them, to many results which have been regarded as great discoveries during the last ten or fifteen years. During the last twenty years, Dr. Thomson has been so constantly before the Medical Public, that it is hardly necessary to refer to the position he occupied in University College, and to his influence as a teacher. His pupils are now scattered all over the world; but, wherever they are, there will not be one of them who will not read this imperfect memoir of him with tears in his eyes, and with the consciousness that he has lost a dear and venerated friend. He was one whose sterling qualities made him loved by every one who came in contact with him; thoroughly honest and straightforward, a warm and earnest friend, ever anxious to advance the interests of his pupils, and constantly endeavouring, promote the wishes of his professional friends, it may be truly said, that there was no man in London more considered by the Profession generally, more cordially esteemed by his colleagues, or more loved and venerated by the students of his class.

As a Practitioner, Dr. Thomson was extremely successful; he was master of the latest improvements in medical doctrines and medical applications, and inspired the greatest confidence in his patients.

Like most men who have deeply investigated physical science, Dr. Thomson was thoroughly imbued with a sense of the majesty of the design and order of the universe. The man who had attempted to penetrate into the nature of the organization of plants, who had entered deeply, at one time of his life, into physiological speculation and chemical research, and who had fixed a curious and profound gaze on the mysteries of disease, could not be otherwise than religious. Dr. Thomson was also a firm believer in revealed religion; and without ostentatious profession, endeavoured constantly to act according to those Divine rules, the truth of which his innate consciousness acknowledged. He thus performed his duties in life worthily and well, he lived at peace with all men, and died tranquilly, leaving to his friends the memory of virtues which cannot be forgotten, and to his Profession a reputation which is in all points untarnished, and an example which might be imitated by every one with profit.

REPORTS OF SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.—June 26, 1849.

Thos. Addison, Esq., M.D., President.

A Paper was read, entitled—

Case of Wound of the Radial Artery, with consecutive Hæmorrhage, treated by Ligature of the Brachial Artery. By H. B. Norman, Surgeon to the St. Marylebone General Dispensary, &c.

J. H., aged 13, thrust his hand through a pane of a window on March 4th, 1848, and inflicted an irregular wound across the fore part of the arm, about an inch above the wrist, which bled profusely. At the Dispensary a compress was secured by a roller passed tightly round the limb, the bleeding having been previously arrested by some temporary measures. The arm became tense and painful in the evening, and the bandage was re-adjusted, less tightly. After the lapse of a fortnight, the wound having partly healed, bleeding recurred. On March 26th the boy lost blood again till he fainted. Compress and bandage were still applied, and the inflamed parts around fomented. On April 1st a third bleeding took place, and on the following day, the hæmorrhage returning, the author was requested to see the patient, and found the lower part of the forearm swollen, tense, and hot; a sloughy opening marked the spot whence the blood had issued, and the surrounding parts were "boggy." Com-

presses were re-applied above and below the wound. In the course of the radial artery, and secured by a lightly-rolled bandage. The constitutional disturbance was augmented on the following day; the integuments about the wound sloughed, giving exit to bloody pus, and strong pulsations were distinctly felt over this part of the limb. The inflamed tissues were now freely divided, a poultice was applied, and a compress placed over the brachial artery. On the 4th, a further hæmorrhage determined the author to ly a ligature on the brachial artery, which was ted without difficulty. The constitutional disturbance continued for some time, but ultimately subsided; the lower wound assuming a healthier appearance, and the patient's diet being improved. The ligature came away on the 8th day, when both wounds were healing steadily. On May 2nd, both wounds were closed, and the boy was convalescent.

The author remarks that he regrets the wounded artery was not exposed in the first instance, and its bleeding ends secured by ligatures. He admits that compression may sometimes be effective where it is immediately resorted to, and great care exercised in its employment; of such practice being successful he cites an instance. He considers the adoption of similar practice to that first referred to (viz., ligature at the seat of injury) in secondary hæmorrhage, a more open question; and observes that, in the case just narrated, the means seem to have been justified by the end, the circulation in both ulnar and radial arteries being arrested, and only restored subsequently in that part of the latter artery which was below the seat of injury. After the application of the ligature, the temperature of the afflicted limb was 2° Fahr. below that of the opposite, on several occasions when the comparison was made.

A Case of Diseased Larynx, in which Tracheotomy was three times performed, and a portion of necrosed ossified Cartilage was coughed up, through the artificial opening from the bronchus. By E. Humby, M.R.C.S.

T. H., aged 53, had passed the greater part of his life at sea, or in the West Indies. In April, 1845, having had syphilis two years previously, he took mercury to relieve secondary pains, &c. In July, a severe cold he caught was accompanied by pains, sore throat, loss of voice, and dyspnœa. Active antiphlogistic treatment proving unavailing in relieving the last symptom, tracheotomy was performed, and a silver tube worn for a month. This was then dispensed with for three weeks, but the recurrence of dyspnœa required its introduction. Mercury was then rubbed in; the patient was kept in a room supplied with a constant jet of steam, and iodine was given internally. In July, 1846, the difficulty of breathing increasing, it was determined that the opening should be enlarged, and a wider tube introduced. This was effected with difficulty by Mr. Liston, in consequence of ossification of the rings of the trachea, which the bone forceps were required to divide. In October following, the author first saw the patient. He was then suffering from constant cough, with muco-purulent expectoration, and great constitutional excitement, with physical signs of mischief in the lungs, especially the left. On November 14, Mr. Liston cut out a second piece of ossified trachea; and, in a fit of coughing which followed, a large piece of necrosed ossified cartilage (apparently a part of the cricoid) was coughed up. The patient died six days after this operation. Autopsy.—The right pleural cavity contained three pints of turbid serum, with lymph. The left lung was partially consolidated. The upper part of the larynx was nearly closed; the back of the cricoid cartilage was absent; the rings of the trachea were ossified; and in the left principal bronchus was a fragment of necrosed ossified cartilage. The author considers the disease to have had its origin in the primary syphilitic affection; and remarks, that the principal points of interest in the case are, the great difficulty attending the operation of tracheotomy in this instance, and the presence of the dead bone in the bronchus.

On the Minute Anatomy of the Sudoriferous Organs. By G. Rainey, Demonstrator of Anatomy in St. Thomas's Hospital.

The Author observes, that the epidermis is composed of two very distinct layers, a superficial and a deep layer; the former consisting entirely of epidermic scales, whilst the latter is made up wholly of epidermic cells, excepting where this layer is perforated by the sudoriferous ducts. These layers are distinguishable from one another by the dark colour of the deeper layer appearing to present an undulating border. The fact of one of the cells being in one layer, and the scales in another, he observes, is contrary to the opinion generally entertained, that the epidermic cells, produced at the inferior part of this layer, become gradually and progressively changed into epidermic scales in proportion as they approach the surface; it also renders the explanation of the cause of the spiral course of the sudoriferous ducts more simple; for, as in this layer, the epidermic scales undergo no change in their structure, and but very little in their dimensions; the duct, being built up of these scales, must remain the same through the entire thickness of this layer as when it first entered it. In the superficial layer of the epidermis the sudoriperous ducts are composed entirely of epidermic scales, so placed that the long diameter of each is parallel with the axis of that part of the passage into which it enters. This part of a duct is destitute of membranous parietes being merely a passage between epidermic scales. In the deep layer of the epidermis the sudoriferous ducts are situated above between flattened epidermic scales, with their long axis placed as before observed, and below between epidermic cells in different states of development. Now as some of the lowest of these cells are so imperfectly formed as scarcely to have the character of cells, it must follow that the part of the passage which is situated between such cells, cannot have its parietes well defined; and there must be a part in every duct (where the cells forming it are just coming into existence) so imperfect that the sweat in entering it will pass through little more than a layer of blastema; it is for this reason that the most inferior part of a sudoriferous duct becomes so indistinct that its termination in the dermic portion cannot be distinctly made out; and it is in this respect that all the delineations of these ducts which I have seen are incorrect, and convey an erroneous idea of their exact structure. The parietes of these ducts are erroneously represented as passing continuously from the dermis into the epidermis; the tube at this part being made to have the same diameter as elsewhere, whilst the fact is that the lower portion of the epidermic part is conical and narrowest below, being shaped like the end of a cork-screw, and the upper part of the dermic portion of the duct is rather conical also, but its base is above. The part of a duct, which is situated between the cutaneous papillæ, contrary to what is generally stated, is, in the place of being straight, very much curved, this being the part in which it gets its spiral form. The dermic portion of the duct is continued from the gland in a flexuous course to the dermic where it terminates, by the membrane of which it is formed becoming continuous with the basement membrane of the papillæ. It is lined by a layer of epidermic cells, which get gradually indistinct towards the gland. Respecting the spiral and conical form of the sudoriporous ducts, it is observed, that this can only be acquired in the deep layer of the epidermis. Since, in the superficial layer, the scales of which they are built up undergo little or no change after they have once been protruded into it, and the dermic portion of the ducts is totally of a different structure to the epidermic. The form which the ducts take in this layer is attributed to the changes which the cells here undergo during their transformation from mere nuclei into perfect cells, and their subsequent conversion into scales, these changes being confined entirely to the deep layer of the epidermis. The ducts here become conical, by the cells which bound them becoming more and more flattened vertically, in proportion as they become pressed upwards, the space between them gradually increasing, as they acquire the form of scales. Besides, this part of a duct is situated in a conical space between the papillæ, where, at its inferior part, the epidermic cells are much more crowded together than at its upper part. This relative difference between the number of cells, and the space containing them would allow of their being more easily separated by the secretion passing between them, above than below. Respecting the spiral form, the increase in the dimensions of the epidermic cells during their growth from nuclei to perfect cells, and their subsequent flattening and conversion into epidermic scales, would have a tendency so to alter the thickness of this stratum of the epidermis, as to throw the passages between its cells into a more or less zig-zag form. As the changes which take place during the formation of cuticle, as well as during that of other structures. do not proceed with perfect uniformity, but are doubtless more active at one period, or in one state of the system, than in another. The Author remarks, that it is probable the laminated form of the nails, the concentric osseous layers around the haversian canals, and the length of the coils of the sudoriporous ducts, are the result of certain alternations of activity and repose of the processes by which they are formed. As there are no other glands in the skin of the hands and the feet, the Author considers the sweat glands, as those which furnish the oily or sebaceous matter with which these parts are anointed; and, in the place of considering the sweat as an increase of the vapour which is at all times given off from the surface, as the insensible perspiration, he regards it as an increased secretion of these sebaceous glands. These glands being in their less active state sebaceous, and in their more active one sweat glands. This must be the case in the hands and feet. The vapour which is exhaled at all times from the skin, whilst in its normal state, he regards as the fluid in which the solid material of the cuticle was dissolved, in order that it might be in a fit state to pass through the coat of the capillaries, having become separated from the solid component of the epidermis blastema during the production of epidermic cells, and having penetrated the scaly layer of the cuticle, would arrive at the surface. In a minute state of division, the fluid part of the sebaceous secretion would doubtless form a part of this vapour.

On the Treatment of Pericarditis; especially on the Effects of Blood-letting and Mercury in that Disease. By John Taylor, M.D., Fellow of the Royal College of Physicians in London, and Physician to the Huddersfield Infirmary.

In this communication the Author has analysed the forty cases of pericarditis, published in the *Lancet* in 1845 and 1846, in respect to the treatment of the disease.

The cases are divided into two classes—1. Those occurring in connexion with acute rheumatism, the subjects of which were previously in good health; and 2. The cases occurring in connexion with renal disease, or in persons in a previously bad state of health.

The patients in the first class, besides being in good health, were younger, and suffered from much fewer complications than those in the second class. Very few of those in the first class died, whereas all died in the second class. The conclusion from these facts is, that the age and previous health of the patients, and the nature of the complicating diseases, have more influence upon the favourable or unfavourable termination of pericarditis than any difference in the treatment.

The remedies, whose effects are examined, are chiefly blood-letting and mercury:—

I. Bloodletting.—The conclusions arrived at are the following:—

1. The duration of pericarditis increases, in proportion as the time is longer between the commencement of the disease and the first bleeding.
2. The duration of the cases bled after the first four days, is greater by one-half than that of those bled within the first four days from the invasion of the disease.
3. The influence of bleeding was more marked in the cases in which it was copiously and repeatedly, as well as early, practised, than in those in which blood was drawn less frequently and more sparingly.
4. Pericarditis is never extinguished at once, by bleeding, however early, or however copiously practised.
5. In several cases the pericarditis was suspended for a limited time. The suspension in every instance was immediately consequent upon the local abstraction of blood.
6. It is probable that renal has a longer duration than rheumatic pericarditis.
7. Blood-letting must be less copious, and is more frequently inadmissible, in renal than in rheumatic pericarditis.
8. Bloodletting probably lessens the mortality, inasmuch as it lessens the duration of pericarditis; but direct proof of the reduction of mortality is not to be obtained from these cases.
9. The abstraction of blood by venesection, cupping, or leeches; almost invariably relieved the pain at once, but not permanently. There is no reason to believe that any one form of bleeding relieved pain more effectually than another.
10. Bloodletting never lessened the frequency of the pulse, except when there were signs of the inflammation having abated.
11. The tendency to syncope, in some cases of pericarditis, renders it necessary to be very careful in abstracting blood by venesection.
12. Free venesection for pericarditis does not always prevent the subsequent appearance of serious inflammation in other internal organs.

II. Mercury.

1. The cases in which mercury was given within the first four days, had an average duration, less by five days, than those in which it was given later.
2. The cases in which salivation was produced within the first four days, had an average duration, less by two days, than those in which it occurred later.
3. It is difficult to determine how much of the benefit was due to the mercury, because all the patients

who took mercury were likewise bled; and, in almost every instance, the two remedies were first employed on the same day.

4. The Author is inclined to the conclusion that the benefit was due, in greater measure, to the bleeding than to the mercury; partly because the duration of the disease was more abbreviated in those who simply began to take mercury, than in those in whom salivation was produced within the first four days. The administration of mercury coincided with the bleeding, but the salivation did not, and the results are just what might be looked for upon the supposition that the benefit was due to the bleeding and not to the mercury.

5. If the production of salivation had anything like the marked influence in arresting inflammation, and in promoting the removal of its products, which it is currently believed to possess, the duration of the cases of pericarditis, after salivation, ought to have been much less than it really was. This is proved by a detail of the cases.

(a) Salivation was not followed by any speedy abatement of pericarditis in sixteen cases.

(b) Salivation was followed by pericarditis in five cases.

(c) Salivation was followed by an increase in the extent and intensity of the pericarditis, in three cases.

(d) Friction sound ceased two days before the mouth became sore in two cases.

(e) Salivation was followed by a speedy *diminution* of the friction sound in two cases; it did not cease, however, for some days after.

(f) The pericarditis *ceased* soon after salivation, in two cases. In one of them, however, it had been declining for some days before.

(g) Mercury was given, but no salivation was produced in seven cases.

(h) No mercury was given, nor other treatment adopted, in eight cases.

(i) Cases are detailed, exhibiting the occurrence of various internal inflammations, during the time that salivation was proceeding. The cases comprise examples of endocarditis, pleuro-pneumonia, pneumonia, pleuritis, erysipelas, and rheumatism.

A conclusion rather adverse to the antiphlogistic powers of mercury having been drawn from the facts narrated, the Author next examines the evidence upon which the contrary and more prevalent opinion is based, and infers that the evidence is not satisfactory. In the course of this examination some remarks are offered upon the necessity for the application of the "numerical method" in therapeutical inquiries, and also upon the difference, and its results, between the practice of French and English physicians, in inflammation of serous membranes.

Case of Chronic Hiccup and Vomiting. Discovery of Oxalic Acid in the Blood. By ALFRED BARING GARROD, M.D., Assistant-Physician to University College Hospital. Communicated by Dr. WILLIAMS.

The Author, after making a few preliminary remarks, shortly described the characteristic symptoms exhibited by the patient, namely, the constant hiccup, or eructation, œdema of the face and extremities, ascites, together with a frequent, but not constant, albuminous impregnation of the urine; and then spoke of the *post-mortem* appearances, of which the only remarkable one was the state of the kidneys, which were found to be coarse in texture, and the tubules of the cortical portion filled with a white plaster-like matter (urate of soda.) Dr Garrod then gave an examination of the blood obtained from the patient, which was found to contain a large amount of urea; and during the search for uric acid, Dr. Garrod discovered the existence of a large amount of oxalic acid in it, which he obtained in the octahedral and dumb-bell form of crystals of oxalate of lime. The Author then described the mode of separating oxalic acid from blood, and stated, that he had succeeded in discovering traces of it in four other cases. Lastly, Dr. Garrod made a few remarks on the importance of the discovery of this acid in the blood, and the probable connexion between the oxalic and uric acid diathesis, and put, as a query, Whether, some of the symptoms exhibited by the patient might not be due to the presence of oxalic acid?

A Case of Calculi of the Pancreas, one of which escaped into the Cavity of the Abdomen, causing Death by internal Hæmorrhage. By OSCAR M. P. CLAYTON.

Mr. J. R., aged 47, an inspector of police, eighteen months before his death consulted the Author relative to frequently recurring dyspeptic symptoms, and a deep-seated pain at the epigastrium. Two or three months later, during an unusually severe paroxysm of pain, hæmatemesis to a considerable amount occurred. The attacks of pain recurred at intervals of two or three weeks, and when severe were followed by more or less of hæmatemesis. Emaciation at the same time slowly increased. His death was attended by symptoms denoting some lesion, probably hæmorrhage within the abdomen.

On examination of the body twenty-four hours after death, coagulated blood in large quantity was found in the peritoneal cavity. The liver and alimentary canal were healthy. But the pancreas was much enlarged, and contained numerous calculi lodged in the dilated trunk and ramifications of the excretory duct. The duct itself presented an opening, through which the largest calculus had escaped into the cavity of the abdomen. This calculus, two-thirds of an inch in length, consisted of carbonate of lime, with traces of phosphate of lime, animal matter, and fat.

A Case of Hemiplegia, associated with Great Hypertrophy of the Heart, and terminating by rupture of the Aorta, producing Dissecting Aneurism. By JAMES R. BENNETT, M.D., Assistant Physician to St. Thomas's Hospital.

A shoemaker, aged 52, was admitted into St. Thomas's Hospital, under Dr. Bennett, on the 27th of February, 1849. His habits had been temperate, and previous health good till within five or six months, during which time he had suffered from palpitations of the heart, vertigo, and uneasiness of the head. Fourteen days before his admission he had an attack of hemiplegia. On his entrance into the hospital he was still hemiplegic, and on examination there was evidence of a greatly enlarged heart; but of no obstruction to the circulation, either pulmonic or systemic. There was a slight diastolic bruit heard just below, and to the right of the left nipple, and there only. His general condition varied from time to time till the 21st of April, when the paralytic symptoms became suddenly aggravated. On the 24th of April he suddenly uttered a cry, indicated that he had pain in the chest, and in three or four minutes expired. Examination *post mortem* revealed an apoplectic clot in the left corpus striatum, surrounded by much softening of the brain, and a similar clot in the centre of the pons varolii surrounded by white softening. All the arteries at the base of the brain, and the smaller branches given off from them, were loaded with atheromatous deposits. In the left pleural cavity there was between three and four pints of recently coagulated blood, which had escaped through a laceration in the costal pleura. This lacerated opening was surrounded by an extensive extravasation of blood beneath the pleura, and the cellular tissue in the posterior mediastinum was throughout infiltrated with blood. On laying open the aorta *in situ*, there was found a transverse rupture three-quarters of an inch in length immediately beneath the origin of the subclavian artery. Above the point of rupture the arterial coats were not separated for more than a line or two in extent; but from this point downwards as far as the iliacs, the artery was split up by the blood which had been forced along between the fibres of the middle coat. Throughout the aorta and its main branches were studded with atheromatous deposits. The heart was enormously enlarged. With the exception of a trifling opacity, all the valves were healthy, as was also the endocardial membrane generally. The coronary arteries were healthy. In structure, both lungs and the pleura were healthy. The kidneys were pale and motled.

The Author remarked on the important chain of morbid phenomena presented by the case detailed, and considered the general arterial disease as the origin of all the subsequent structural changes both in the heart and brain. The patient appeared never to have had any arthritic disease, and there was nothing to indicate that the heart or pericardium had ever been the seat of acute or chronic inflammation. The hypertrophy of the heart was therefore referred to the loss of elasticity of the aorta, &c.; but it was suggested, that the aortic valves might, in consequence of the force to which they were subjected, have allowed some regurgitation, and the existence of a diastolic bruit was supposed to favour such a view. The augmented nutrition of the heart, and the healthy state of the coronary arteries were contrasted with the condition of the brain and its diseased arteries.

Dr. Kingston: In connexion with this case, it may be worth while to mention one with which I am acquainted of dissecting aneurism, as illustrative of another condition of system which it may give rise to—another condition of the arteries. The patient was a lady, about seventy-six years of age; and as in the interesting case communicated by Dr. Bennett, there was the coincidence of hemiplegia, with dissecting aneurism; but they were only connected by their proceeding from the same cause. In my case, the aneurism took place in the descending aorta, about half an inch below the innominata, so as completely to block up its orifice.

The President: It is a question how far the diastolic bruit was indicative of aneurism. To me it appears strongly indicative of it, being below the nipple. A very short time ago I saw an instance of it. The aneurism was seated behind the heart. But I doubt its being the result of injury to the valves.

Dr. Theophilus Thompson: One point of value connected with the paper is, that it is an illustration of such an event taking place, in the absence of those causes which generally give rise to it. There was no decided rheumatic affection, or affection of the aorta. The loss of elasticity of the middle coat of the aorta is dependent generally on inflammation; but here there were no symptoms of inflammation about the aorta. Again, there was no rheumatism. Then, on what did it depend? I think we may assume, that it arose from premature old age of that particular membrane. The appearances are very similar to those presented in old age; and in the absence of any symptoms of inflammation, and the presence of symptoms of senile degeneracy, I think mine is a fair assumption. Another point is, the connexion of the disorganization of other parts. It is most evident that the changes in the brain took place before the laceration of the coats of the artery, but this deficiency was favourable to the softening of the brain. I would remind the Society of the case of Moret, a physician, one which is brought forcibly before my mind by the paper read. It resembled that case, in that there was considerable softening of the brain, and paralytic symptoms, which subsided, and ultimately issued fatally, accompanied with rupture of the aorta, and the escape of pints of blood into the pleural sac. It was thought that disorganisation of the brain occurs by the effusion of blood between the two layers of the middle coat of the artery. Indeed, there was reason to think that this condition had existed for some days; and certainly this case seems to favour the opinion, that a condition of artery leading to laceration may often occasion softening of the brain and clots,—that, the paralytic symptoms may subside, and that the cause of it is preliminary disease of the artery. While the paper was being read, I was on the look out particularly as to whether there was any existence of pain about the abdomen; in some cases violent pain in that region is complained of.

The President: I only wished to express my opinion that we had here a very valuable diagnostic description of the disease. The bruit was heard below the left nipple, and on that symptom alone I should have been led to anticipate aneurism. The diastolic sound here was heard clearly in the same situation; and I am of opinion that was produced by the passage of blood through the aneurismal sac.

Dr. Bennett: There was no aneurismal sac here; only a dilated state of the aorta. With respect to any pain about the abdomen, it is stated in the paper that he felt a craving at the pit of the stomach, and fancied that he required more food; but he certainly never had any severe pain. There was no aneurismal sac previous to the rupture which caused death.

Dr. Williams: It is not uncommon to hear diastolic murmurs at, below, or above the nipple; the distinctness of them depends more on the position of the heart, or the overlapping of the lung. I have heard the murmur almost exclusively to the right of the nipple.

Mr. Blackall considered it very remarkable, that the heart should be dilated to such an extent as in this case, without the patient suffering any symptoms of disease.

Dr. Peacock wished to inquire of Dr. Bennett whether the competency of the aortic valves had been tested by the action of a column of water before the orifice was divided; if this was not done, it was difficult to decide whether there was, or was not, any regurgitation. Though considerable general hypertrophy of the heart was frequently seen, without any material valvular disease, he thought such an extreme amount of hypertrophy and dilatation of the left ventricle, as existed in this case, very rarely

occurred unless there was regurgitation through the aortic orifice, and the murmur heard during life rendered it probable that there had been some deficiency of the valves, allowing a column of blood to flow during the diastole from the aorta into the ventricle. He had recently investigated the subject of dissecting aneurism in connexion with a case which had occurred to him, and he found that by far the largest proportion of cases which were reported, were similar to that of Dr. Bennett, the laceration of the internal tunic of the artery which allowed of the formation of the aneurism being usually soon followed by the rupture of the external wall of the sac. There were four or five cases on record in which the tearing of the internal coats occupied a similar situation; and there was also one case in which the blood had escaped into the left pleural cavity. In Dr. Bennett's case, the rupture of the vessels in the brain was antecedent to the formation of the aneurism; but, in some cases, the sudden obstruction to the flow of the blood, caused by the pressure of the aneurismal sac, occasioned a second rupture of some other part of the vessel. This occurred in two cases which fell under his own notice, and in one related by Mr. Guthrie. In other instances, one or other of the cavities of the heart had given way, as in the case of George II. Dr. Bennett's case confirmed an opinion which he had expressed relative to the seat of the sac in cases of dissecting aneurism. He believed that it would generally, if not always, be found to be situated in the laminæ of the middle coat, and not between the external and middle coats, as had been generally supposed. He had performed experiments on the aorta, with a view to this point; and found that the external coat, alone, does not possess sufficient power to resist a column of fluid injected beneath it. In several cases which he had carefully examined, in the recent state, the sac was situated between the laminæ of the middle coat, and in two which he had dissected, and which had been previously published as dissecting aneurisms with the sac between the middle and external coats, he found that a layer of the middle coat was sound, with the external coat forcing the outer wall of the sac.

Dr. Bennett: The valves were examined with very great care; and were it not for the sake of being accurate, no allusion would have been made to the slight condition of them. I should like to call attention to the practical question which has been mooted by Mr. Blackall; it is certainly of great importance to ascertain the history leading to the assumption that there is aneurism; but, being ignorant of this in the present case, I looked upon the aneurism of the heart in connexion with hemiplegia, and looked on it with interest as a consequence of hypertrophied heart. The man was only cupped once over the cardiac region.

Dr. Thompson: In the case before referred to, there was hypertrophy, and in that case the valves were perfectly healthy; the aorta was somewhat dilated, and there was hypertrophy of the left ventricle, with a natural condition of the aortic valves.

Dr. Bennett said, that in reference to the experiment mentioned by Dr. Peacock, it had not been tried in the present case.

In closing the meeting, and also the session, the President expressed his hope that the very large assembly of gentlemen which he then saw before him was but an earnest of the growing prosperity of their Society.—Adjourned to November.

REVIEWS.

Lectures on the Causes and Treatment of Ulcers of the Lower Extremity. By George Critchett, Esq., F.R.C.S., &c. &c. London: John Churchill.

Having carefully perused Mr. Critchett's work, we were at a loss to discover the Author's object in publishing it; but, on turning to the Preface, we there found it stated that "the Author's main object, in the publication of this little book, is, to place the principle of mechanical support, in the treatment of ulcers of the lower limbs, on a correct and scientific basis; although, as he has endeavoured to show, this has already been briefly done by the late Mr. John Scott, in his work "On Diseased Joints;" a reference to all the best surgical authorities, since that work appeared, proves how entirely that principle is still, if not unknown, at least most imperfectly expounded; but, in addition to this, the Author has devoted considerable attention, during the last ten years, to the treatment of this class of diseases, and has had extensive opportunities of testing the practical value of the principle he advocates, and also of arriving at certain rules with regard to its applicability to the various phases which the disease presents, and the modifications required in order successfully to cope with the peculiarities of special cases." Our Author adds:—"He has, therefore, been anxious to offer the Profession such rules as he has been able to work out and has found useful in his own practice, and such as he has reason to believe would have considerably facilitated and rendered far more successful his own early efforts in this branch of surgery."

The principle of mechanical support in the treatment of ulcers of the lower extremities we have long believed to be well understood by all practical surgeons. We well recollect how strongly it was insisted on by Mr. Abernethy in his lectures; and we can testify that it was constantly applied in his practice. The very course recommended by Mr. Critchett was followed by Mr. Abernethy. The application of the strapping in all cases in which there was a varicose state of the veins, always commenced at the toes or some part of the foot, and in some cases it was carried as high as the knee, but in others not so far, and, according to its height, it used to be jocularly called, a "*half*," or a "*whole boot*." But from our Author's testimony, we must suppose that this part of surgery is neglected by Professors of the present day, and if that be the case, without doubt he is justified in calling the attention of the Profession to the subject.

It is not only the "varicose ulcer" which is considered in the work before us, but also ulcers of every denomination to which the lower extremities are subjected. The Author states:—"I propose, in the first place, to divide all ulcers into simple or local, specific or constitutional. I again divide the single or local into acute or spreading, sub-acute, chronic, healthy, irritable, and varicose; the specific, or constitutional, I arrange under the various heads of strumous, syphilitic, phagedenic, periostal, menstrual, œdematous, and malignant."

Our Author gives his own views on the nature and treatment "of each of these classes of ulcer," and moreover adverts to most of the remedial plans which have been proposed.

The means of cure recommended by Messrs. Baynton, Skey, Syme, Spence, &c., are separately considered, and objections, more or less well founded, made to each. His condemnation of Mr. Skey's plan is most decided, and in the following terms:—"Mr. Skey's pamphlet, emanating from so high a quarter as St. Bartholomew's Hospital, promised such great things, and with so much confidence, from the use of opium in the treatment of ulcers, that I was surprised to find, after a prolonged and extensive trial, that in no one instance I was able to trace the slightest benefit from its use. I have carefully administered this drug in about forty cases of this kind, and I have been compelled to arrive at the conclusion, that it is utterly valueless as a healing agent in the treatment of ulcers of the lower limbs."

But in the treatment of "each of the classes of ulcer," Mr. Critchett is most enthusiastic in his recommendation of mechanical support, by means of "strapping," in fact, he considers it the *ne plus ultra*; for, in conclusion, he states, "I must ever believe it constitutes the best and most efficient remedy yet discovered."

We by no means concur in all that is stated in the work; but there is much of it worthy of consideration, and we can conscientiously recommend it to the careful perusal of our junior readers.

We certainly hope to hear what Mr. Skey has to say to the charge brought against him by Mr. Critchett, of having advocated an "utterly valueless" mode of treating ulcers of the lower limbs.

Life Assurance: An Historical and Statistical Account of the Population, the Law of Mortality, and the different systems of Life Assurance; including the validity and non-validity of Life Policies; with Observations on Friendly Societies and Savings Banks; to which is added a Review of Life Assurance, explanatory of the Nature, Advantages, and the various purposes to which it may be applied. By Alfred Burt, Esq., Secretary to a Life Office. London: Effingham Wilson. Pp. 211.

There is little need to insist, in the columns of a medical periodical, on the importance of the subject of this book. The proverbial uncertainty of human life is a proposition which every one assents to the instant it is mentioned; and one may perhaps add, that the urgent necessity of making some provision for survivors is an act which, though many may defer, few would absolutely avoid. As the most unhealthy, laborious, and ill paid of the three learned professions, that of Medicine experiences far more than its share of those sad contingencies which Life Assurance is mainly intended to remedy. But, even apart from this personal interest in the question, its members are so intimately connected with it in a professional capacity, and so often applied to for advice on the subject, that it is scarcely too much to say that it behoves all of them to know at least the main features of Life Assurance, and the circumstances which should indicate the selection of this or that particular office.

The impossibility of gathering solid and trustworthy information from the multitudinous figures and *ad captandum* arguments of advertisements has hitherto rendered this subject, to the many, rather obscure and uncertain. The deficiency thus existing this book is intended to supply, and we can only say, that if all books were equally preceded by a want, and equally supplied that want, there would be far fewer volumes furnished from the Press; the skimmers of books might perhaps read them, and, haply, some of the readers might even aspire to understand them.

The book is a slim volume of pages 200 octavo. And the cynic who, on hearing that the Author is Secretary to a Life Office, is prepared to find it a flagrant advertisement of *the* Office, will be agreeably or disagreeably mistaken in learning that the author very properly withholds the name of his Office from the title-page, and affords no clue to it in any part of the volume.

In an introductory chapter, the stability of Life Assurance Societies is especially insisted upon. Reference is made to results which show, that, with with the exception of attempts at gross imposition, no instance of a failure has been known. This *acute* disorder excepted, it would appear that Life Assurances are remarkably *healthy* schemes; that the blood, we beg pardon, the money, circulates slowly and equably through their system; that the ingesta must counterbalance, or nearly so, the egesta; and, finally, that the continuance of their germ power is pretty sure to develope a bonus.

After a chapter upon Population, the Author successively treats of the laws of mortality and the nature of life assurance. The latter, which of course forms the chief part of the book, occupies three or four chapters. Under each of these heads the reader will find a very full account given of the history of the subject, as well as of its present position and bearing upon the question of Assurance. We think the Author has been very successful in making a complicated matter, involving many figures and calculations, so far intelligible as to be mastered with little trouble by the general reader. The different methods of Assurance, the different bases of Societies, the scales of premium, and the mode of payment, all receive due attention, and a very fair index points out at once any one of these for reference. He plainly considers that, on the whole, the best Society is a Mutual one, of some standing, and with as frequent as possible division of the profits. Next to this would come a young Mutual Society, with a small subscribed capital. Then would follow the mixed Mutual and Proprietary schemes, which offer part only of the profits to the subscribers; and, finally, as the least eligible,

except to the proprietors, follow the Proprietary Societies, in which the whole, or nearly the whole, of the surplus of revenue over expenditure is divided by that fortunate body of men—the large capitalists.

As regards diseased lives, there is of course little to be said. It would appear, however, that there is singularly little variation in the mortality of the diseases, consumption and others, which have at present been investigated with this view. But we take leave to differ slightly from the Author, and doubt whether the duration of phthisis, much less of any other disease, is either well known or accurately calculated for.

We cannot help remarking here, that there are few things which would tend more to increase the advantages of Assurance and extend its benefits, than a careful selection of medical advisers. Many a man is a very fair practitioner of medicine who is utterly devoid of the nice diagnostic skill necessary in a medical officer to an Assurance Company. We could add many curious anecdotes on this head, but will content ourselves with reminding Insurance Offices, that even now their medical officer is their most important and worst-paid functionary, and that a little more care in his selection would often add a large balance to the profit side of their accounts. As to the remuneration of the Medical referee, that is a question which some Offices have already decided, and they deserve the gratitude obviously due to those who pay for what they buy, and do no more than their duty. The other Offices must soon adopt the same plan, or if not, the Profession hold the decision in their own hands, and are becoming daily more unanimous on the subject.

On the whole, we are disposed cordially to recommend this book to our readers as an authority on the subject of Life Assurance. It is full, simple, and well arranged. It will enable any one with ordinary care to understand the subject, and to choose the special Office which offers, in his particular circumstances, the greatest advantages.

An Inquiry into the bearing of the Earliest Cases of Cholera, which occurred in London during the Present Epidemic, on the Strict Theory of Contagion. By Edmund A. Parkes, M.D., &c., Pp. 28.

An Account of the Origin, Spread, and Decline of the Epidemic Fevers of Sierra Leone, with Observations on Sir Wm. Pym's Review of the "Report on the Climate and Diseases of the African Station." By Alexander Bryson, M.D., R.N. Pp. 174.

There is no subject connected with our Profession at the present moment more deeply interesting than the question of the contagion of epidemic diseases. Proving fatal to vast numbers of the community in a few hours, they demand attention with a voice so loud, that there are few who, when they are the subject of discussion, do not lend an attentive ear. Quarantine laws, having for their object the exclusion from among us of such epidemic diseases as are contagious, involve in the obedience enforced to them the sacrifice of so much individual comfort, and of what is of far more importance in the minds of not the least influential of the community, such vast pecuniary losses, that no class, and scarcely an individual, but from sense of personal danger, or the hopes of medical success, must watch the progress of medical knowledge on this subject with the keenest interest.

We have conjoined the above works because they both enter somewhat fully into the subject of contagion, and the authors of both agree in the conclusion to which they have arrived, that diseases which owe their origin to endemic causes may become contagious.

The latter of these works, although ably written, is a sad example of the ill-feeling which medical controversy, even in the present age, can excite. Dr. Bryson and Sir Wm. Pym would, it seems to us, have supported their own dignity, the credit of the Profession, and the cause of truth better by indulging less in personal abuse. The pages of these two gentlemen recall to our minds Touchstone's quarrel with the courtier:—

"Jaques: Can you nominate in order now the degrees of the lie?

"Touchstone: Oh, Sir, we quarrel in print by the book; I will name you the degrees. The first, the retort courteous; the second, the quip modest; the third, the reply churlish; the fourth, the reproof valiant; the fifth, the countercheck quarrelsome; the sixth, the lie circumstantial; the seventh, the lie direct."

The use of "If" appears to have entirely escaped these authors—*If*, the only peace-maker, as the witty fool calls it.

The following extracts will, we think, justify us in what we have here stated:—

"*False* version." "*Perversion* and distortion of the real state of the case." "From the *false* and erroneous statements of Sir Wm. Burnett." "He (Sir Wm. Burnett) had some malicious object in view."—Sir Wm. Pym's Observations.

"These egregiously absurd complaints and accusations, made by the medical chief of the quarantine are, I submit, *not very creditable as regards his own character* for consistency." "Why, one might suppose that he (Sir Wm. Pym) had been smoking hachisch, or following the example of Rip Van Winkle," &c., &c.

"Hence his (Sir Wm. Pym's) real or *pretended* astonishment." "*Not true, he knew this when he wrote it.*" "This paltry libel." "The peculiar position in which Sir Wm. Pym has placed himself with respect to his *veracity*."—Bryson's Account, &c.

And all this calling of hard names is because these gentlemen differ on a purely scientific question; Sir Wm. Pym asserting and believing, and his assertion is supported, be it remembered, by very high authority, (we may, among other Authors, mention Dr. Stevens,) that there are two diseases confounded under the term "yellow fever." The one, "the Bulam fever," "Bulam with vomito negro," "African typhus," as Dr. Stevens terms it, contagious; the other, a non-contagious, endemic, remittent fever, accompanied, like the former, more or less frequently, with yellowness of the skin. These Writers have in their favour the weight of *à priori* reasoning, and the authority of great names. Dr. Bryson, on the other hand, represents a party who believe that non contagious remittent yellow fever, due for its origin to endemic causes, malarious otherwise, may be converted, in its passage through the human frame, into contagious, continued yellow fever. The weight of evidence, *so far as it goes*, is in favour of these Authors. So that, in the present state of knolewdge, a man may hold either in one opinion or the other without being guilty of professing wittingly his belief in a lie.

We are surprised that some one of the many able men who visit the quarter of the world where these fevers prevail, does not give to the Profession a series of cases of both forms of disease, so that we who cannot see might at least judge. At present the *ipse dixit* of Sir Wm. Pym is placed against the *ipse dixit* of Dr. Bryson, *i.e.*, using these gentlemen's names as representatives of parties; and, "I say it is," is only opposed by, "I say it is not," or, less politely, by "You lie." From these combatants we turn with pleasure to the pamphlet of Dr. Parkes, in which the subject of the origin of cholera in London is treated with that ability, candour, temper, and scientific precision which characterize all his literary productions. The importance of the subject, the peculiar facilities Dr. Parkes enjoyed for conducting the investigation, the simple elements with which he had to work, and the honesty of purpose which evidently guided him in his researches, lead us to attach so much value to this paper, that we shall offer our readers a tolerably full abstract of its contents.

The "Inquiry" commences with a lucid and concise statement of the question at issue between the two parties, the opinions of which respecting the diffusion and propagation of epidemic diseases, our Author believes, divide the Medical world—*i. e.*, that of the strict, and that of the modified contagionists. To the strict *non*-contagionists Dr. Parkes assigns no place, apparently believing, that such a sect has no existence. The Non-medical Board of Health, it will be remembered, have retracted the heresy contained in the first *famous* Gwydir-house Manifesto. The following extracts will give our readers some notion of the mode in which the question is stated:—

"The *strict contagion theory* I take to be that which refers epidemic diseases to the action of specific poisons, which (it alleges) multiply themselves only during their passage through the animal body. All other reputed modes of increase this doctrine considers to be doubtful or untrue; and it looks upon the external circumstances which surround the animal frame as influencing the efficient cause or poison of the epidemic, only so far as they render the body a more or less fit recipient for its action. As it concludes that the body is the only source from which a fresh supply of the specific agent can be evolved, it deems it necessary that the person, to be infected, should come within the influence of the particles of poison (imparted by contact, diffused in the air, or adhering to clothes,) which have been emitted from the breath, surface of body, or excretions of an individual already suffering from the disease, or from the corpse of one who has already died of it. . . . .

"While the influence of epidemic constitutions of the atmosphere, and of external local circumstances, over the fevers of this country, as over the Oriental plague, is admitted, these conditions are presumed simply to augment the susceptibility of the subject, but to have no direct influence on the virus itself. They act on the soil which is to receive the plant, but they do not heighten the inherent force which is normal to the seed. To explain certain special cases, which seem strongly opposed to such a view, and which point to the development *de novo* of the specific virus, the advocates of the strict contagious theory have attributed an extraordinary durability to the poisons of fever and of plague, and a power of lurking within the frame unaltered until the accessory causes have prostrated the force which at first successfully resisted them. . . . . .

"*The theory of modified contagion*, in seeking to determine the mode of non-contagious propagation, considers, with the greatest attention the media external to the human body, which surround the particles of any special poison. It regards the humidity and temperature of the air, its purity, its electrical condition, the weight of its column, and the movement of its masses. It questions what may be the exhalations from the soil, from decaying substances, from all the various natural or artificial peculiarities which vary the surface of the ground. In all these circumstances it sees a twofold action—an action upon a virus introduced among them—an action upon a human frame submitted to them. It seeks to determine what relative assemblage of these conditions is most favourable to the spread of a poison; it believes that, under its favouring conditions, some poisons introduced *ab externo* may augment by reproducing themselves. It goes even further than this; in certain cases, it sees, in an intense concentration of these several circumstances, a development *de novo* of that specific poison which is proper to that particular assemblage of conditions. On the banks of the Ganges it witnesses the cholera poison spring into existence; in the swamps of Batavia, the malignant intermittent passing into remittent; on the river marshes of Western Africa, the deadly remittent, from which springs the epidemic yellow fever; among the effluvia emitted from our great cities, or among the miserable hovels of a starving nation, the fever-poisons of this country; among the Fellahs of Egypt, with their peculiar rites of sepulture, and their pernicious customs of social life, the poison of bubo-plague. It attaches, also, much importance to the consideration of the occasional, and even periodical, augmentations in the vigour of the specific poisons, believing that these are partly dependent on influences exerted on these poisons by 'epidemic constitutions' of the atmosphere."

Having thus stated the general question at issue, our Author observes that Asiatic cholera manifestly belongs to the most strongly marked order of epidemic diseases, and then lays down with precision the object of his Paper.

"In the following inquiry, I do not intend to enter on the general subject. I am simply desirous of placing on record the evidence respecting the first cases of cholera in London, and to inquire particularly into the possibility of these cases having arisen from contact or proximity with persons already diseased.

"The strict contagionist theory has always considered that strong evidence in its favour was to be obtained from a study of the early cases. It claims to be always able to point out the channel of introduction,

and to trace the first steps of the malady; afterwards, when the sick have become numerous, it considers that persons may be exposed to emanations, and may sicken, without being aware that they have been so exposed. At this late period, therefore, the proofs of contact or proximity cannot be obtained; and negative evidence loses its value.

"The first twenty-five or thirty cases are then, in this point of view, most important. Did they arise together, or near each other? Were they exposed to sources of contagion, from which the other inhabitants of the district were exempt? Can each successive case be traced to a prior case, until the patients are too numerous to be followed up?"

And then the laws to be observed in weighing evidence:—

"It is necessary in examining evidence on this point to adopt two precautions.

"1. Every reputed case of the disease must be known.

"2. Every reputed case must be inquired into, and its exact nature determined; the loose accounts of by-standers and non-professional persons not being received as credible evidence."

'Having shown that he has in the "Inquiry" complied with these rules, Dr. Parkes proceeds to give brief notes of the first twenty-eight cases of true cholera which occurred in London during last autumn; and here, we must say, we wish the cases had been given at greater length. The brevity of these notes is the only fault we have to find with the paper and it puzzles us to conceive, why, as Dr. Parkes must have had the materials in his possession, he did not publish them. A few, two or three, pages more print, would have afforded all that could have been required. The following was the first case of true cholera:—

"The Elbe steamer left Hamburgh on the 22nd of September, and arrived in the river on the 25th. A seaman, named John Harnold, left the vessel, and went to live at No. 8, New-lane, Gainsford-street, Horsleydown. On the 28th of September he was seized with symptoms of cholera, and died in a few hours. It is stated in a letter to the General Board of Health, from Mr. Russell, who attended the patient, that all the characteristic symptoms of Asiatic cholera were present. Mr. Bowie, who inquired on behalf of the Board into the particulars of the case, corroborated this statement. This may then be considered as an undoubted case of cholera."

Dr. Parkes has arranged the twenty-eight cases he is considering, all of which, it will be observed, occurred in twelve days, in the subjoined Table:—

Date.		Locality.	In Contact or not with a Person labouring under Cholera.
Sept. 28..	John Harnold	Horsleydown	With the mate of his vessel, who was said to have died of cholera—case not certain, with cholera patients in Hamburgh.
Sept.	John Murphy	Lambeth	Not in contact with any cholera patient
„	Richard Cook	Chelsea	Ditto ditto ditto
Oct.	Jane Langham	Harp-court, Fleet-street	Ditto ditto ditto
	Owen Jones	Justitia Hulk, Woolwich	Ditto ditto ditto
	James George	Lambeth	Not known to be in contact with any cholera patient
	Daughter of above	Lambeth	In contact with her father
	Susan Cook	Chelsea	In contact with Richard Cook
	An old man	Horsleydown	Not known to be in contact with any cholera patient
	Robert Gordon	Dreadnought, Greenwich	Not in contact with any cholera patient
	John Healey	Lambeth	In contact with John Murphy
	Joseph Hill	Chelsea	Probably in contact with Richard and Susan Cook
	Mary Ann C.	Spitalfields	Not in contact with any cholera patient
	Sister of above	Spitalfields	With her sister
	William Cook	Chelsea	In contact with Susan Cook
	Son of above	Chelsea	In contact with his father and mother
	Elizabeth Morris	Chelsea	With the above
	John Rutherford	Justitia, Woolwich	With Owen Jones
	— Rabett	Dreadnought, Greenwich	With Robert Gordon
	James Bigwood	Justitia, Woolwich	With Owen Jones and John Rutherford
	Louisa Hill	Chelsea	With Joseph Hill
	James Paterson	Pool	Not known to be in contact with any cholera patient
	Rouse (a sailor)	Pool	Ditto ditto ditto ditto
	Mother of Mary Ann C.	Spitalfields	With her daughters
	James Baker	Bermondsey	Not known to be in contact with any cholera patient
	David Davison	Pool	Ditto ditto ditto ditto
	A convict	Justitia, Woolwich	With the convicts mentioned above
	A man, aged 41	Prescott-street, Clapham	Not in contact with any cholera patient.

"Horsleydown lies on the south side of the Thames, to the eastward of Bermondsey, and is situated close to the river, at a point nearly opposite to that where St. Katharine's Docks are placed. From Horsleydown to Lambeth, by the river, is a distance of several miles, as the Thames here makes a large curve. As the crow flies, however, Horsleydown is about two miles distant from Lambeth, or rather from Lower Fore-street, where the second case of cholera occurred. The two spots are separated by the districts of Bermondsey and Southwark, which compose an immense city, crowded with inhabitants. The spot in Chelsea, in which the next case occurred, is on the other side of the river, and close to Battersea-bridge; it is, in a direct line, about two miles from Lower Fore-street, Lambeth, and four from Horsleydown. Harp-court, Fleet-street, is in the City of London, about half way between Temple-bar and Ludgate-hill, and is separated from the Thames by the breadth of Fleet-street, and the length of the lanes running from Fleet-street to the river. As the crow flies, it is about two miles, or one mile and a half from both Horsleydown and Lambeth. It is about four miles from Chelsea. Woolwich is situated about eight miles from Horsleydown, ten from Lambeth and Fleet-street, and twelve from Battersea-bridge. The Dreadnought Hospital-ship lies off Greenwich, about three miles above the Justitia, and five from Horsleydown. Spitalfields, Clapham-common, and Bermondsey are also districts widely separated from each other. The spot in Bermondsey, in which the case occurred on the 9th of October (eleven days after John Harnold's case), was at the part of Bermondsey most remote from Horsleydown."

Having shown that the disease sprang up in these ten localities quite independent of personal intercourse, our Author next inquires, whether the two individuals, Owen Jones and Robert Gordon, residing respectively on board the Justitia and the Dreadnought, and who, by no stretch of the imagination, can be conceived to have held personal intercourse with infected persons, could have been exposed to some other source of contagion; and having satisfactorily disposed of this question in the negative, Dr. Parkes asks, Can any modification of the strict contagion theory explain the origin of these cases? To this also, after a most impartial examination of the facts, he answers in the negative:—

"The scrutiny to which these cases have been submitted, proves, that in the greater number of the localities—in all, in fact, except Horsleydown—the poison was not imported by any person ill of cholera arriving in the locality. Nor could it have been brought by the clothes or baggage of any persons coming from infected districts in England, as there were no infected districts from which such persons could have come. There is no evidence either of any persons arriving from the Continent, from Hamburg, or from Dantzic, to these localities. If such persons did arrive in London, it is most probable that they were connected with the shipping, and were, therefore, many miles removed from Lambeth, Chelsea, and the other places in question."

Our Author thus sums up—

"I may remark, in conclusion, that I have desired merely in this Report to apply the strict contagion theory to these early cases. I have decided that this theory cannot explain them. I have done so not merely on negative evidence that no contact or proximity between these early cases could be traced, but on positive testimony, that such contact or proximity was impossible. These cases are, then to be accounted for on other grounds; into these, however, I shall not at present enter more fully; contenting myself with the remark, that it appears to obable that the cholera poiso have entered the localities first infected by virtue of some peculiar force acting irregularly and partially, so as to drive the poison into one rather than into another locality;—or that the poison should have been actually generated in those localities under the influence of a general atmospheric condition cooperating with the local conditions proper to each place, than that it should have reached those localities by direct emission from diseased individuals in the vicinity or at a distance, or from clothes which had been in contact with infected persons.

"I feel, however, that, without enlarging my basis of inquiry I have no right to push this argument further. To do so with any effect, facts drawn from a more extensive series of observations would have to be passed in review.

"Whether or not the evidence which has satisfied my own mind will prove as satisfactory to others, I do not know; but I can affirm, that I have collected this evidence with impartiality, and have stated it with sincerity."

Would that all writers on the question of contagion could with equal *truth* declare, that their evidence had been collected with impartiality.

UNIVERSITY DEGREES.

[To the Editor of the Medical Times.]

SIR,—An anonymous correspondent in your last Number, whose experience of University education is evidently of a very limited character, endeavours to enlighten his Professional brethren as to the relative merits and value of the degrees from the various British Universities. He particularly singles out Edinburgh for *disparagement*, and *puffs up* St. Andrew's. Edinburgh enforces four years' University study, and gives a fair and strict examination, which it requires more than average attainments to pass. If your correspondent will look over the list of eminent provincial physicians, he will find nine out of every ten are Edinburgh men. *The business of diploma-granting* at St. Andrew's commenced when I was a student in Edinburgh, when many of the *private teachers* were made *Professors*, and their pupils, as a matter of course, passed their examinations at St. Andrew's with great *eclát*, and got their cheap diplomas without the trouble and expense of a regular graduation at the University of Edinburgh. I was solicited by a Professor, but preferred staying two years longer to obtain a degree I should not in after life be ashamed of. No doubt, many eminent English surgeons have since found their way to St. Andrew's to obtain a degree at little expense and no loss of time; but the examination alone is no test of a person's abilities, for I have known the most ignorant passed at St. Andrew's by a few weeks' grinding. Whilst such men as Alison, Christison, Syme, &c., fill the Edinburgh chairs, the degree of M.D. from that University will never be considered second-rate.

I am, Sir, your obedient servant,

S. D. LEES, M.D. and F.R.C.P. of Edinburgh, M.R.C.S.L. and L.A.C.L.

Ashton-under-Lyne, July 7, 1849.

VACCINATION AND UNION SURGEONS.

[To the Editor of the Medical Times.]

SIR,—It has been my intention for some months to address a few lines to you on the subject of vaccination, and to expose its mode of practice as at present conducted, which, if continued, seems not a little calculated to degrade the Profession more than anything that has occurred for some years past. One of your Correspondents some months ago proposed that the Poor-law Unions should pay all medical men for vaccination. This is scarcely to be expected, nor would it be at all desirable on their present terms: persons might as well expect the Legislature to provide payment for other minor operations in surgery. Another of your Correspondents about the same time said, that 1s. 6d. was too little to be paid for the attention required for such operation; consequently, the smallpox was on the increase. In this I quite agree. But the facts I wish to point out are simply these:—That in some parts of Yorkshire (and I should suppose it to be much the same in other counties), many of the Union surgeons have stated *that they only* are empowered to *vaccinate by authority*, not only paupers, but the children of all other persons, and in this way they very frequently obtrude their services on their neighbours' patients unsolicited, offer to

vaccinate their children gratis, or for some small fee, when at the same time they enter them in their returns to the Board as successful cases to be paid for by the Union as paupers, however respectable the parties may be, or whether they are paid a higher fee or not at the time. They are not prevented by the present law from being paid twice, but, if not always so fortunate, it gives them an excellent opportunity of appearing *most generous, very considerate, and kind-hearted*, and it has often been a considerable means of their attending such family afterwards, should an opportunity occur. The consequence is, that the neighbouring practitioners are now frequently compelled to vaccinate the children of private and respectable patients *gratis*, to prevent such obtrusions on their practice. One of these kind gentlemen called upon a lady, the patient of a friend of mine, a short time ago, to inquire who was her medical attendant, as he wished to present him with a glass of very fresh lymph, just taken from the arm of Lady ——'s son. Of course, the object of this visit was quite apparent, and the offer very properly declined. I think if the Legislature had provided for the paupers only, the other portion of the community would have paid their own medical attendants for vaccination, as they did before the Unions were established. This appears to be the most reasonable way of settling the present vexatious mode of practice. I may mention, that, when vaccination was first introduced, many of the old surgeons charged 10s. for each child in a respectable family, and 5s. for humbler classes. Though it is an operation requiring very considerable care and attention, we are now very frequently obliged to perform it gratuitously in self-defence. This, I hope, Mr. Editor, is another instance of the necessity of a speedy reform in our Profession, and also that a more liberal system of payment may be adopted by its respectable members, who are so frequently called upon to perform urgent services to their fellow-creatures without the slightest prospect of any remuneration.

I am, Sir, yours obediently,

VERITAS

MEDICAL NEWS.

APOTHECARIES' HALL.—Names of gentlemen who passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, 5th July, 1849:—Daniel Meadows, Wetnesham, Suffolk; William Byron Hill, Exeter, Devon.

ROYAL COLLEGE OF SURGEONS.—The following gentlemen having undergone the necessary examinations for the diploma, were admitted members of the College at the meeting of the Court of Examiners on the 6th instant:—Messrs. Edward Batwell, Charleville, county Cork; Hugh Cuolahan, Great George-street, Bermondsey; Henry Welsh, Grenada, West Indies; Walter Murray Sedgwick, Antigua, West Indies; Samuel Henry Hobart, Cork; William Prowse, Bristol; William Garrard, Bristol; Robert Ingram Stevens, Islington; George Evans, Seaton, Devon; George Peacock, Dublin; and Charles France, London.

APPOINTMENTS.—Mr. Ryder, late of Greenwich, has just been appointed Resident Surgeon of the Royal Kent Dispensary, Deptford, in the vacancy occasioned by the lamented decease of Mr. W. Arundel Burridge.

COLLEGIAL ELECTIONS.—At a meeting of the Council of the Royal College of Surgeons on Thursday afternoon, for the election of officers, &c., Mr. Joseph Henry Green, F.R.S., and Surgeon of St. Thomas's Hospital, was elected President; and Messrs. James Moncrieff Arnott, F.R.S., Surgeon to University College Hospital, and John Flint South, Surgeon to St. Thomas's Hospital, were elected Vice-Presidents of the College for the ensuing year. At the same meeting, Messrs. Hodgson and Wormald took their seats as members of the Council.

OBITUARY.—On the 5th ult., at Funchal, Madeira, Dugald M'Kellar, Esq., M.D, formerly of Battersea, Surrey.—On the 4th inst., at Chertsey, Sir John Chapman, F.R.C.S., late of Windsor, aged 78.—On the 10th inst., in Albemarle-street, in the 67th year of his age, Sir William Hyde Pearson, M.D., F.R.S.

MEDICAL REFORM AND THE LORD ADVOCATE'S BILL.—We have been informed, upon good authority, that the Government proposes to introduce into the House of Commons, even at this late period of the session, a Bill for the better regulation of the Medical Profession. It is not the intention of the Lord Advocate to proceed with the measure during the present sitting of Parliament, but simply to place the Bill before the Profession and the country. We consider this a most judicious proceeding, as Medical men will have an opportunity of well considering every clause, and, by the meeting of Parliament next spring, to have organised their forces either to oppose or support the Bill. It has been intimated to us that it contains many excellent clauses in favour of General Practitioners.

THE CHOLERA.—This disease has been spreading in London and the provinces. At Liverpool, Manchester, Worcester, Portsmouth, and some other large towns the mortality has considerably increased, and is attributed to "cholera." In the metropolis it has appeared again at the Milbank Penitentiary, and continues to cut off its victims in the neighbourhood of Bermondsey and Rotherhithe. It has been stated, that persons living in the vicinity of graveyards are especially liable to attacks of cholera. We know this to be true, yet every parish burying-ground in the metropolis is continually receiving additions of putrifying animal matter to its already surcharged soil. The Bishop of London is said to have refused to prohibit the interment of bodies in the Farringdon-street burying-ground, surcharged with corpses, and in a neighbourhood where the cholera has made its appearance. The disease still continues in Blackfriars; and Mr. Houlding, surgeon, at an inquest held on Wednesday evening last, stated, that many cases in other parts of the town had arisen in persons who had spent a greater part of the day in Blackfriars. We subjoin the Registrar's report for the week of the health of London. The whole mortality is rather high, as compared with the numbers returned from week to week, during the last two months. There is an obvious increase in deaths caused by zymotic or epidemic diseases, with a decrease, though not to an equal extent, in those produced by affections of the respiratory organs. In the former class, during the last three weeks, the deaths have been progressively 277, 349, and 393; the latter, the numbers in the same weeks were respectively 119, 105, and 87. Hooping-cough numbers 47, or double the usual amount of fatal

Diarrhœa increases a little; but the deaths from it which last week were 46, have not reached the average of the season, which is 76 for in the previous years, chiefly in a more advanced part of the quarter, this complaint has carried off many children of tender age. In the corresponding week of 1846 the deaths from diarrhœa were 70. Two cases are reported of children who died,—one of diarrhœa, another of hydrocephalus, at No. 3, Linney-court, Museum-street, where the back of the house has no windows, and the smell from drains, and other nuisance in front, is extremely offensive. The average at this season, from cholera, is only 8; its recent progress is shown by the deaths in the last six weeks, which were successively, 9, 22, 42, 49, 121, and, in last week, 152; namely, 94 of males, and 58 of females. Of the 152 victims of this disease, 19 were under 5 years of age, 30 at 5 and under 15 years of age, 88 between 15 and 60 years, and 13 at 60 and upwards. The ages of 2 are not returned. It is worthy of observation, that not more than 14 deaths from cholera, last week, occurred in the west and northern districts, though the population which they comprise is about a third of the whole. On the south side of the Thames there were 93; and in this region the districts of Rotherhithe, Lambeth, and Bermondsey are fatally distinguished. Other epidemics differ, at present, not much from the average. A young man died of "want" in Camden-town, and an infant of "exposure to the night air and purpura hæmorrhagica," in the Borough-road sub-district. A man of 48 died of "paralysis from working in a lead-factory, after an illness of 13 weeks." Mr. Butterfield, the registrar of Islington East, has recorded what he describes as "a curious fact," but without stating his authority, that women, employed in this manufacture, last much longer than men.—[This statement is worthy of attention.]

MR. JUSTICE COLTMAN died on Wednesday morning. His Lordship was taken ill on Monday last, with cholera, as we understand, and on Tuesday night was found to be in so exhausted a state that his life was despaired of.

THE PROVINCIAL MEDICAL ASSOCIATION.—The Thirteenth Anniversary of the Lancashire and Cheshire (hitherto Newton) branch of the Provincial Medical and Surgical Association, was held at the Albion Hotel, Manchester, on Thursday week. In the absence of the President for the year, Robt. Thorp, Esq., (who was prevented attending by indisposition,) the chair was occupied by Sir Arnold Knight, M.D., Liverpool. Amongst the members and visiters present, were, Dr. Lyon, Dr. C. W. Bell, Mr. Turner, Dr. Radford, Dr. M. A. E. Wilkinson, Mr. Hatton (hon. sec.), Dr. Pincoffs, Mr. Whitehead, Mr. Williamson, Mr. Dorrington, Mr. Lambert, Dr. Black, Mr. Lund, Mr. Crompton, Mr. R. H. M'Keand, Mr. John Kirkman, Mr. Richmond, Mr. Winterbottom, and Mr. Bowring, Manchester; Dr. Macrorie, Dr. Watson, Mr. Burrows, Dr. Dickinson, and Mr. J. A. Pearson (Vice-President), Liverpool; Mr. Flint, Stockport; Mr. Sharp, Warrington; Mr. Wilson, Runcorn; Mr. Fawsitt, Oldham; Mr. R. Rigge, Woolton; Dr. Broughton, Preston; Dr. Welsh, Eccles; Mr. Halkyard, Mossley; Mr. Mauley, Tyldesley; Mr. Pegge, Newton Heath; Mr. Brooke, Stockport; Mr. Darcey, 30th Regiment; and Mr. E. Inge. After the business of the meeting was transacted, and several interesting subjects connected with the Profession discussed, the gentlemen present sat down to a sumptuous dinner.

QUEEN'S COLLEGE, BIRMINGHAM.—At the meeting of the Council, held on Tuesday, July 3rd, the Rev. Chancellor Law, the Vice-Principal, in the chair, Mr. George Bellasis Masfen, of Stafford, was enrolled in the list of Fellows, under the provisions of the Supplemental Charter. Mr. George Bellasis Masfen distinguished himself as Warneford Medallist for the year 1847.

PRIVATE LUNATIC ASYLUMS.—At a meeting of magistrates, held last week at Gloucester, a most animated discussion took place in reference to the private Lunatic Asylums in the county. A Report was read by the Chairman, in which he recommended some very important alterations in the government of private institutions for the insane. We will advert to the subject more at length next week.

TESTIMONIAL OF ESTEEM.—On Monday we k a gold watch, with appendages, was presented to Walter M. Kelly, Esq., Surgeon, Leadgate, by the workmen of the Derwent Iron Company, as a tribute of gratitude for the valuable professional services of that gentleman. It is not often that we have to record instances of public respect like this to the members of our Profession. The tribute of gratitude to Mr. Kelly, coming, as it does, from "workmen," must be highly pleasing to that gentleman, for it is a testimonial of more real value, in a moral view, than splendid services of plate presented by the affluent to their favourites.

SEAMEN'S HOSPITAL-SHIP.——The "Dreadnought," lying off Deptford, is ordered to Woolwich, to be docked and examined, in order that a better provision may be made for ventilating her lower deck. The patients are to be sent on board the "Iphigenia," late Marine Society's receiving-ship, and the "Devonshire," which latter vessel is now lying alongside, where it will remain during the time the "Dreadnought" is being repaired.

PUBLIC HEALTH BILL FOR SCOTLAND.—We understand that information, founded on authority which may be relied on, was received in Edinburgh on Monday, that the Public Health (Scotland) Bill had been *dropped* for the Session.

MORTALITY TABLE,

(Metropolis.)

For the Week ending Saturday, July 7, 1849.

Causes of Death.	Total.	Average of Five Summers.
All Causes	1070	1008
Specified Causes	1066	1005
Zymotic (or Epidemic, Endemic, and Contagious) Diseases	893	302
Sporadic Diseases:		
Dropsy, Cancer and other Diseases of uncertain or variable seat	36	44
Tubercular Diseases	173	190
Diseases of the brain, Spinal Marrow, Nerves, and Senses	115	119
Diseases of the Heart and Blood-vessels	38	29
Diseases of the Lungs, and of the other Organs of Respiration	87	81
Diseases of the Stomach, Liver, and other Organs of Digestion	68	76
Diseases of the Kidneys, &c.	8	11
Childbirth, Diseases of the Uterus, &c.	11	7
Rheumatism, Diseases of the Bones, Joints, &c.	6	7
Diseases of the Skin, Cellular Tissue, &c.	1	2
Malformations	1	3
Premature Birth and Debility	16	22
Atrophy	26	25
Age	32	43
Sudden	17	8
Violence, Privation, Cold, and Intemperance	38	36
Causes not Specified	4	3

The following is the number of Deaths occurring from some of the more important special causes:—

Apoplexy ...	16	Heart	[illegible]	Phthisis	126
Bronchitis ...	35	Hooping-cough	[illegible]	Pneumonia ...	38
Cholera	152	Hydrocephalus	27	Scarlatina	13
Convulsions ...	11	Influenza	2	Small pox	3
Childbirth	4	Lungs	4	Stomach	2
Diarrhœa	46	Liver	13	Teething	11
Dropsy	11	Measles	20	Typhus	16
Erysipelas ...	8	Paralysis	18	Uterus	7

BIRTHS AND DEATHS.

	Births.	Deaths.	Births over Deaths.
Males ..		566	69
Females	642	504	138
Total	1277		

METEOROLOGY OF THE WEEK.

	Mean of Barometer.	Mean of Thermometer. Dry.	Ditto. Dew Point.	Difference between the Mean Temperature of the day and the same day on an average of 7 years.	General Direction of Wind	Amount of Horizontal Movement of the Air.	Rain in Inches.	Positive and Tension moderate. On Jul
Sunday ..	29·900	60·2	47·4	+0·9	N.N.W. and	[illegible]	[illegible]	[illegible]
Monday.	[illegible]	[illegible]	[illegible]	[illegible]	N.	[illegible]	[illegible]	[illegible]
Tuesday.	[illegible]	[illegible]	[illegible]	[illegible]	S.	[illegible]	[illegible]	[illegible]
Wednesd	[illegible]	[illegible]	[illegible]	[illegible]	N.	[illegible]	[illegible]	[illegible]
Thursday	[illegible]	[illegible]	[illegible]	[illegible]	S.	[illegible]	[illegible]	[illegible]
Friday ..	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
Saturday	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]

TO CORRESPONDENTS.

Our friends overwhelm us with kindnesses. The quantity of the communications we receive, assures us our endeavours to administer to the *real* wants of the Profession, so far as journalism is concerned, are fully appreciated, while a daily increasing subscription-list evidences, that honesty and integrity of purpose, fearlessness of consequence in exposing wrong, and an anxious endeavour to give praise and support when merited and due, will ever meet with reward, and the substantial support of all "good men and true." If, however, we are sometimes backward in replying to our friends, they must occasionally bear with us, and rest assured, that their suggestions seldom fall in barren places.

Again, certain of our friends are in the habit of writing to us in a half private, half public manner. This is very inconvenient, since we can neither avail ourselves of their communications in the pages of our Journal, nor find time to reply to them privately. It is also injurious to our readers, since much valuable matter is thus rendered useless. We have also to request, that all communications intended for the Journal may be addressed to the Editor, 117, Strand, London.

We will attend to Dr. Barker's request, which, however, we had not forgotten.

"Chirurgus," on University Degrees, will receive a place in our next Number.

"Mr Blench's" cases of dry cupping in intermittents will be published. It always gratifies us to find our notices of foreign practice responded to at home.

"Chirurgus," in a note to our publisher, requests to be informed as to the best mode of preparing the fluid extract of Taraxacum, the time of year the Dandylion should be gathered, the part of the plant used, &c. &c. All these questions he will find answered in any pharmaceutical text book. We can, however, assure him, he can save himself much trouble, if not expense, by purchasing the extract ready prepared. And we recommend him, if he still requires practical information, to pay a visit to Mr. Hooper, operating chemist, Pall-mall East, with whose mode of preparing vegetable extracts *by cold*, we think he will be as much pleased as we ourselves have been.

"A Reformer of Abuses" forwards us a communication on Medical Education. We have received it at too late a period to offer an opinion, or to make any promise for its publication.

"Dr. Venable's" interesting paper on Hæmaturia and its diagnosis, will appear next week.

"R. C." can obtain information concerning any German University by addressing, post-paid, a letter to its Rector, in English if he pleases.

"A. B." next week.

"J. M. Meath."—The metallic brush is an instrument recommended by Westring for applying the galvanic current to any particular part. It consists of a plate of ebony fitted to another of gold, in which are fixed thread of the same metal. The instrument is connected with a voltaic battery.

"Neo-chemicus"—(1) Scheele discovered that oxalic acid could be artificially formed from any organic substances by means of nitric acid. (2) Starch and sugar are mixed with from eight to ten times their weight of nitric acid, and heated in a water bath. Solution takes place readily with evolution of nitrous acid. After concentration and refrigeration, chrystalized oxalic acid is obtained, to the amount of one-sixth part of the weight of the materials employed.

"M. B." Admission tickets to the library of the College are not transferable.

"A College Member"—Members of the Apothecaries Company are those who constitute the incorporated society; licentiates, those who have, obtained the certificate to practise as apothecaries

"A St. Thomas's student."—The appointment of assistant-surgeons in the army rests with the Director-General, Sir James McGrigor, to whom a letter should be addressed. (2) Assistant-surgeons in the navy receive their appointments from the Lords of the Admiralty, upon the recommendation of the Director-General, Sir William Burnett, before whom the candidates have to pass an examination.

"Theodore, Manchester"—The disease is dependent upon a peculiar irritability of the retina, produced by two different causes,—a sudden exposure to a stronger light than the eye has been accustomed to sustain; and a deficiency of the pigmentum nigrum.

"An occasional Correspondent"—The surgeons of the last century recommended the use of the actual cautery; but if the tumor is thoroughly removed, with some of the sound parts, there is no danger of the disease returning.

"Counterblast" wishes to know if it is really a fact that tobacco smoking is a prophylactic against cholera. Such a statement has been made, but we are disposed to think without any good foundation.

"M.R.C.S, Lond."—The degree of M D. is derived from so many sources, that we are unable to give our correspondent the information he demands.

Mr. A. B." 1. Senile gangrene is sometimes rapid in its progress. Any respectable work on surgery will furnish an answer to the second question.

A Physician" is of opinion, that no Medical Reform Bill will be complete which does not provide that youths, previously to entering the profession, shall undergo a strict examination in the classics. He thinks, that early discipline of the mind the better fits it for the after study of abstruse sciences.

A. M., Bradford.'—Hydrocyanic Acid, perfectly pure, can not be preserved; it decomposes spontaneously, whether exposed to the light or kept in the dark; a small quantity, however, of sulphuric or hydrochloric acid prevents decomposition.

"Medicus" is right in the statements he has made. The letter, however, is too long for insertion. The question of the propriety of a repeal of the tax upon light and air has not been overlooked by sanitary reformers. There is no doubt that the present window duties act injuriously upon the poorer classes by limiting the number of windows in their houses. Air and light are as essential to health as an abundant supply of pure water and well-constructed sewers.

"Hibernicus" would not be able to practise in London.

"Leon."—We know of no remedy for the disease.

"Anglican."—Degrees in medicine at the University referred to are conferred at two stated periods annually, viz., at the end of April and July.

"A Subscriber, Hackney."—Chronic acites, we believe, has been successfully treated by tincture of iodine injected into the peritoneum. We have not, however, had an opportunity of seeing any cases in which it was employed.

"M.D. and an Old Subscriber."—The symptoms of apparent weakness should not lead to inactive treatment; but energetic anti-phlogistic measures should be adopted to relieve the inflammation which constitutes the physical cause.

"A Medical Practitioner."—The artificial inflation of the lungs of a child born dead may cause them to float in water.

"Galen."—The average time at which death takes place in poisoning by arsenic is probably about twenty-four hours; but life, of course, may be destroyed in a much shorter time.

"A Student, Bristol."—In the French Codex Medicamentorum, liquids are used by weight.

"Lector."—Of the true nature of electricity nothing is positively known.

"F. L. G."—Yes Esquirol attached great importance to the suppression of certain cutaneous affections as a cause of insanity

"Edinburghensis."—At present, great doubts on the subject exist.

"Civis."—An application, addressed to the President through the Secretary, with a recommendation of two members belonging to the Society, would be the means of a respectable applicant effecting his object.

"Inquirer"—There are several good elementary works on the science mentioned by our correspondent. By naming one in particular, we should unfairly advertise it.

"Δ."—The diploma of the College of Surgeons would be sufficient.

"A Country Subscriber."—We know of no specific for the cholera. Should our correspondent be so fortunate as to discover one, we shall be happy to give it an early announcement in the "Medical Times."

"J. —."—The Reports must be forwarded before we can give an opinion of their suitableness for publication.

"Chemist" should consult Paris's Pharmacologia, where the formula is given.

"Medico Chirurgus" ought not to place any reliance on the statement alluded to.

"G., Cardiff."—No alteration has yet been made in the Physician's Charter.

"Vindex."—It would be illegal, and the person would subject himself to penalties.

"M.D. Edin."—The Commissioners would not sanction the appointment.

"George."—1. The Parisian diploma of M D. is a difficult one to obtain. 2. It would not entitle the possessor to practise as a physician in England.

"Mr. Hall"—In answer to both questions, No.

"Q. S" shall receive an answer next week.

"Nem"—We have no doubt of the correctness of our Correspondent's remarks, but must decline publishing the letter

We have received a letter from Mr. Churchill, respecting a notice in a late Number, of Mr. Dalrymple's excellent Work on the Eye, in which we stated, that "were the price less we did not doubt it would become as much in vogue as Mackenzie's work on the same subject." Mr. Churchill totally mistakes the bearing of these remarks. We were very far from thinking the work in question to cost more than it was worth—on the contrary, we think it, as a book, cheap; and so we stated it to be, saying it was "above price" to the country practitioner. But still the price, although small in comparison with the value of the book, is too high for the Profession generally; in fact, they cannot afford to purchase it. Book societies, however, have this advantage, that they enable the many to read and to consult that which the few cannot aspire to possess.

A "Mr. J. O. Browne" writes us very cleverly and jocosely upon the plague of skin disease books which has lately fallen upon the profession. Although he proposes a strange remedy—brandy and salt—we shall publish his letter, with a few remarks of our own.

"Medical Provident Institution."—We had prepared some observations upon this new Proposal. Press of matter, however, leaves no room for them in the present Number.

We have many volumes waiting for review. Amongst others we hope soon to be able to notice—

Mr. Noad's Lectures on Electricity.
Dr. John Scoffern, on the Manufacture of Sugar.
Mr. Stanley, on Diseases of the Bones.
Dr. Bennet, on Inflammation of the Uterus.
Mr. Wade, on Strictures of the Urethra.
Professor Meig's Treatise on Obstetrics.
Professor Owen's Works on Parthenogenesis, and on the Nature of Limbs.
Mons. Dubois' Traité de l'Art des Accouchements.
Dr. Addison, on Consumption and Scrofula.
Dr. Robert Lee, on Diseases of the Uterus.
Dr. Carey, on Cod Liver Oil, &c. &c. &c.

We hope next week to review the contents of the "Phychological Journal" for the July quarter.

ORIGINAL LECTURES.

HUNTERIAN LECTURES.

ON THE

GENERATION AND DEVELOPMENT OF THE INVERTEBRATED ANIMALS.

By RICHARD OWEN, F.R.S.,

Hunterian Professor and Curator of Museum of Royal College of Surgeons, Corresponding Member of the Institute of France, &c.

[Reported expressly for the "Medical Times," and revised by the Lecturer.]

LECTURE IX.

GENERATION OF ENTOZOA. — Succession of Trematode individuals under different forms and grades of structure from the multiparous ova. Spontaneous fission of Microstomum and Planariæ. Multiplication of the latter by artificial division. Diœcious generation of ACANTHOCEPHALA. Testes and their axial mesorchium: varicose sperm-ducts, sperm-vesicle, prostates and penis. Numerous free ovaria; oviducts and uterus suspended from a mesometrium: their active movements. Development of the uncinated embryos of the Echinorhynchus. All the Cœlelmintha diœcious. Generative organs of the fluke-like Linguatula. Capillary type of the testes and ovaria in the NEMATOIDEA. Testes and sperm-duct a single continuous tube in all: penis double in some species. Various forms and appendages of preputium. Ovaria and oviducts continuous; usually double. Rachidian arrangement of ova, and their enormous number in the *Ascaris lumbricoides*. Various situations of the vagina in different species. Development of Ascaris and Strongylus. Viviparity and metamorphosis of the Guinea worm. Probable larval nature of *Trichina spiralis*. Bearing of the known generative phænomena of Entozoa on the hypothesis of spontaneous generation.

When the Entozoologist contemplated the *tænia* fixed to the intestine, with its uncinated and suctorious head buried in the mucous membrane, rooted to the spot, and imbibing nourishment like a plant, when he saw the sluggish *Distoma* adhering by its sucker to the serous membrane of a closed internal cavity, he naturally asked himself how got they there? And finding no obvious solution to the difficulty of the transit on the part of such animals, he was driven to the spontaneous-generation hypothesis to solve the difficulty. It is no wonder that Rudolphi and Bremser, who studied this instructive class rather as Naturalists than Physiologists, should have been led to apply to them the easy explanation which Aristotle had given for the coming into being of all kinds of Vermes, viz., that they were spontaneously generated. No other explanation in the then state of the knowledge of development of the Entozoa appeared to be adequate to account for the fact of their getting into the interior cavities and tissues of higher animals. Subsequent researches have, however, shown that the tape-worm quits the ovum as a minute locomotive *Echinococcus*; and that, when it finds its way into the interior of the alimentary canal it is already provided with six uncinated organs for the purpose of attaching and fixing itself. The chances against the introduction of such a minute ovum or embryo are, of course, great, but these impediments are met by the incredible numbers that are developed in a single individual of the *Tænia* and *Bothriocephalus*. The mode of introduction of the *Entozoa*, of the order *Trematoda*, becomes in like manner more intelligible as the phenomena of their development are better understood. Certain fresh-water snails are infested by Entozoa of this order, as the *Limnæa stagnalis, e.g.* by the *Distoma tarda*. The ova, or products of the ova, of this species are found in early summer, adhering in vast numbers to the inner surface of the respiratory cavity, and to the exterior of the lobes of the liver and generative organs of the snail; where they increase in size, and detach themselves as free animalcules, assuming a bright yellow colour, whence they were called by Bojanus "konigsgelben Wurmern," and manifesting a twisting vermicular motion. If one of these be microscopically examined, none of the lineaments of the organs of the future *Distoma* can be discerned; they resemble in structure rather the *Gregarinæ*, consisting, in fact, of little else than the cell-progeny of the primary germ-vesicle. Few of the cells have perished as such, or have been metamorphosed, save those that have gone to form the outer contractile skin, whilst still fewer have been liquefied and absorbed into a larger subcentral cell.

As the growth of this Gregariniform parasite proceeds, a progeny is seen to rise in its interior by the development of several of the contained germ-cells into embryos; these gradually acquire a cephalic spiculum and a caudal appendage; they escape from the parent cyst and from the snail, and disperse themselves as free swimming ciliated cercariform animalcules in the water. After a brief enjoyment of this free and active state of existence, they shrink in size, the vibratile tail is cast off, and they attach themselves to the skin of the snail. Here they become buried, form for themselves a pupa-case out the condensed mucus, and are metamorphosed into true *Distomata*, which gain their parasitic habitat by piercing the soft integument of the water-snail. Thus we have a Trematode entozoon, successively assuming the form of a *Gregarina*, a *Cercaria*, and a *Distoma*; many individuals under the two latter forms being developed out of one impregnated ovum.

Professor Siebold has traced the metamorphoses of another species of *trematoda* up to a certain point, the rest being made intelligible by the analogy of the trematoda of the snail. He found that certain water-fowl were, at particular seasons, infested with a small kind of fluke worm, the *monostoma mutabile*. Rudolphi and others had described them in the alimentary canal; Siebold likewise found them in the air-cells of the abdomen. He discovered this species to be viviparous, and observed the act of bringing forth, when the *monostoma* was placed in cold or luke-warm water. The ova and embryo are developed as in the tænia. The first germ-cell appears in the midst of a thick granular germ-yolk; it multiplies, and its progeny, as they become smaller, and more numerous, break through or divide the yolk, and finally consume it. The embryos escape from the vulva, close to the penis, and swim briskly, while the egg-shells fall to the bottom. Sometimes an egg was excluded, containing the embryo, which soon escaped. It is 1-9th of a line in length, of a long oval shape, with a truncated head and a rounded tail-end. On the upper part of the head are a pair of square dark pigment-spots, which reminded Siebold of the eyes of the cercaria. The smooth ciliated integument includes a delicate parenchyma, laden with granules, and in the centre a clear, colourless, firm body, answering to what the nucleus is in the ordinary cell. This body was pointed at one end, enlarged, and with three short thick processes at the other. But he was surprised to find that this body, in the inside of the embryo, presented distinct and independent movements, so that he had here no fewer than three creatures successively included in one another: the monostoma in the water-fowl, the embryo in the viviparous monostoma, and the smooth triradiate contractile organism in the embryo. After the ciliated larvæ had swam about for some time, they sometimes sank to the bottom, with the fore part motionless and dead, while the hind-part still contracted and exhibited the ciliary movements. Some embryos would thus swim by the hinder half, whilst the fore-part was decomposing into its component granules; and, at length, the little smooth triradiate firm body comes forth entire, exhibiting feeble motions. After its escape, it begins to show an extremely fine granular structure; but not a trace of a proper organ. Here Siebold's observations were arrested. He asks if this can be regarded as an accidental parasite of the embryo; but remarks, that it is too constant an occurrence. He did not meet with one embryo without it. He was, also, struck by its resemblance to the "King's-yellow worms" of Bojanus. Steenstrup, however, has resumed and pursued the inquiry. He found that this gregariniform organism grows rapidly, after having first attained their proper element, the water. But how do they get into the water? It is supposed, that the trematode embryos, by means of their cilia, work their way either from the intestines, per anum, or through the abdominal air-cells and trachea, and escape by the glottis and mouth into the water, and there liberate the gregariniform organism. Here we have the next series of changes. The fine nuclei or granules with which its parenchyma abounds, become the centres of a series of developments which result in the whole creature being made a parental cyst for some scores of cercariæ. The metamorphosis of such cercarial larvæ into trematode worms, has been repeatedly witnessed by good observers. If any Cercariæ are swallowed with the water by the water-fowl, then, of course, we have a ready mode of accounting for the presence of the monostoma in the alimentary canal. Or a Cercaria taken into the mouth might pass down the undefended glottis, and so get to the lung or air-cell; or it might insinuate itself into the infra-ocular cell of a diving-bird, where also the *Monostoma mutabile* has been found.

Steenstrup cites the successive stages of active and independent life that are manifested between the ovum and the oviparous or viviparous trematode worm as examples of "alternate generation;" the cercariform being is the "amme" or nurse of the trematode worm; the "king's yellow-worm" or gregariniform being is the grand-nurse "grossammo;" the ciliated monadiform larva is the great-grand nurse. This is an exposition of the main facts in figurative language, but is not an explanation of them. What we require are the conditions of structure, which give or admit of the power of procreation without the coitus or act of impregnation in the procreating animal. They appear to be these; and they are revealed by examining the structure of the entozoon in question in the several stages of its genetic cycle, comparing them with each other and with the changes operated in the ovum by the reception therein of the spermatic principle. In the development of the monadiform larva of the monostoma or distoma, either the vitelline membrane is metamorphosed into the ciliated skin of the larva, or this is formed by the metamorphosis and coalescence of the peripheral layer of the germ-mass. But, admitting the latter process, no other parts of that impregnated germ-mass are changed excepting those which form the external contractile and ciliated integument; there is no mouth, no stomach, or other internal organs, and no members; the only change which has taken place in the impregnated germ-cells is rather a kind of change of the relative position of the essential spermatic or clear nuclear matter, which has become aggregated in the centre of the locomotive larva, which may be compared to the locomotive germ or spore of an alga or sponge. It is, in fact, a single celled animal with a ciliated as well as a contractile cell-wall.

In a short time after it has escaped from the ovum the ciliated integument ruptures, and its contents disappear, with the exception of the concentrated nuclear matter, which is left clear and distinct, and of a definite form. A spontaneous movement is observed in this body: it grows, and now a granular structure may be seen in it under a high magnifying power. Before its escape it seems to be a compact structureless mass; but afterwards numerous points or centres of independent force begin to operate, and give rise to multitudinous minute granules or nuclei, and it takes on a structure comparable to that of the Gregarina. Now, what is the condition of this second phase or form in the metagenetic progress of the entozoon?

It will be observed, that the embryo of the monostoma, when it quits the ovum, is not like the chick; the primary germ-cells have not been converted into numerous and diversified tissues and organs; the great majority of them remain unchanged, and without exhaustion of the spermatic force. This force would seem to be concentrated in the clear nucleus, which expands to constitute the smooth-skinned Gregariniform worm. In this, as in the pseudo-navicellar capsules, numerous unchanged germ-cells or nuclei set up as many centres of development, from each of which a cercariform embryo results. In this process, many of the germ-cells and nuclei are metamorphosed into organs, and a corresponding proportion of the spermatic force is exhausted. What remains serves to govern the subsequent developments, which result in the change of the individual Cercaria into a

Monostoma or a *Distoma*; this is a metamorphosis; but the antecedent phases should rather be called a matagenesis, and the conditions essential to that act are the retention of a due proportion of the primitive germ-mass unchanged, and with its primarily received spermatic force unexhausted.

Some of the Trematode Entozoa are remarkable on account of the places they are found in; for instance, some species, as the *Diplostoma volvens*, infect the interior of the eye of the perch and other fishes. The pupa of this species has been found in the eye of the perch, coiled up, adhering to the inner side of the cornea, and then there has been observed an oblique line, or trace in the cornea, which shows how it bored its way through to get there. But frequently it does not get so far, and one finds such pupæ in cases like a watch-glass adhering to the skin or conjunctiva outside the eye. It is probable that different stages of the *Diplostoma volvens* have been described as distinct species, and that the *Holostomum cuticola*, Nordmann, is the pupa, and Diplostomum clavatum, the larva of the same species.

A few words with regard to the Planariæ. These creatures have the outward form and inward structure of the trematode entozoa, only that they retain throughout their life the little eye-specks and ciliated skin which characterise the larva *Monostoma*. In general, the alimentary cavity presents such an organism as we find in the *Distoma hepatica*. The female organs are well developed and they propagate by ova. But it has been observed that they present a greater number of unchanged nucleated cells and nuclei; and co-existing with these is the power of propagating by spontaneous fission, and also the power of recovering from injury, and of redeveloping the entire animal from a severed part. But the ordinary development is by ova; and it is remarkable to watch the instinct of these animals during oviposition; although they have no limbs, they take the ova as they are excluded, but covered with a gelatinous fluid, which they draw out into threads, and thus fix the ova to the stems of little aquatic plants. All this is done by the flexible and extensile mouth and neck.

Proceeding next to the higher orders of the Entozoa, all these are diœcious, or of distinct sex. The males are smaller than the females, and always less numerous. The first of these orders is the *Acanthocephala*. The worms of this order resemble the Nematoid Entozoa in outward form, and in the distinction of the sexes, but in their digestive system they still manifest the sterelminthic type.

The species of this order constitute but one genus, *Echinorhynchus*, characterised by a more or less elongated, round, sub-elastic body, the head having a retractile proboscis armed with recurved spines. The *Echinorhynchi* abound in the lower animals, and are some cylindrical, and others sacciform. The largest known species (*Echinorhynchus gigas*) infest the intestines of the hog. As regards the tegumentary and muscular system, it resembles the Nematoid worms, as well as in its diœcious generation; but its digestive system is very different, and somewhat obscurely developed. The mouth is a minute pore, situated on the extremity of the uncinated proboscis: it leads to two long cylindrical canals, which adhere to the muscular tunic, and are continued to the posterior extremity of the body, where they terminate in blind ends; and two shorter cylindrical cœca are continued backwards from near the mouth, and are freely suspended in the anterior part of the generative cavity: they are called *lemnisci*. The male organs consist of two fusiform testes, two varicose vasa deferentia, which unite together to terminate in a single vesicula seminalis, and a long intromittent organ provided with a bursa copulatrix, occupying the posterior extremity of the body, and having a special muscular apparatus for the retraction and extrusion of the contained organ. The male organs are suspended by a "mesorchium" from the base of the proboscis. The male echinorhynchus is generally half the size of the female. The generative organs in this sex consist of several ovaries, which are masses lying free in the general cavity of the body. The ovaries are long and wide cylindrical canals, extending from the proboscis, to which they are suspended by a mesometry, as far as the tail, and the common slender oviduct terminates at that extremity by a very minute pore. The ovum and germ-mass are developed as in the tænia, and the little embryo has four spines.

The *Acanthocephala* constitute a limited, yet natural order. The *Linguatulæ* (*Pentastoma* of Rudolphi) are the type of an analogous circumscribed groupe with a higher type of organization, which entitles them to rank in the class *Cœlelmintha*. This class includes all the cavitary intestinal worms of Cuvier, with the exception of the "Vers ridigules" or Epizoa, which are proved by their metamorphoses to belong to the siphonostomous Crustaceans.

The order *Nematoidea*, which forms the chief part of the class *Cœlelmintha*, must chiefly interest the medical practitioner, since it includes the principal internal parasites of the human subject: viz., *Trichina spiralis*, *Filaria medinensis*, *Filaria oculi*, *Filaria bronchialis*, *Trichocephalus dispar*, *Spiroptera hominis*, *Strongylus gigas*, *Ascaris lumbricoides*, and *Ascaris* or *Oxyurus vermicularis*. To the order *Nematoidea*, repeated examinations, since my first observation of the minute *Trichina spiralis*, induce me to refer that singular microscopic parasite. I have satisfied myself of the accuracy of Dr. Farre's and Dr. Henle's description of the distinct alimentary canal. In a specimen of *Trichina* now under the microscope, a loop of the intestine may be seen protruding through a rupture of the abdominal wall. The vermicule is always contained in a cyst. The occurrence of these cysts in vast numbers in the muscular tissue was made known in a very interesting case published by Mr. Hilton; and many others have since been recorded.

The cysts are very readily detected, by gently compressing a thin slice of the infected muscle between two pieces of glass, and applying a magnifying power of an inch focus. They are of an elliptical figure, with the extremities more or less attenuated, often unequally elongated, and always more opaque than the body or intermediate part of the cyst, which is, in general, sufficiently transparent to show that it contains a minute coiled up worm. The usual size of the cyst is 1-50th of an inch in the long diameter, and 1-100th of an inch across their middle part. The cysts are always arranged with their long axis parallel to the course of the muscular fibres, which probably results from their yielding to the pressure of the contained worm, and becoming elongated at the two points where the separation of the muscular fasciculi most readily takes place, and offers least resistance.

The innermost layer of the cyst can sometimes be detached entire, like a distinct cyst, from the outer portion, and its contour is generally well marked when seen by transmitted light. By cutting off the extremity of the cyst, which may be done with a cataract needle or fine knife, and gently pressing on the opposite extremity, the Trichina and the granular secretion with which it is surrounded, will escape; and it frequently starts out as soon as the cyst is opened.

When first extracted, the Trichina is usually disposed in two or two and a-half spiral coils; when straightened out, it measures 1-30th of an inch in length, and 1-700th of an inch in diameter, and now requires for its satisfactory examination a magnifying power of at least 200 linear admeasurement.

The worm is cylindrical and filiform, terminating obtusely at both extremities, which are of unequal sizes, tapering towards one end for about one-fourth part of its length, but continuing of uniform diameter from that point to the opposite extremity.

Until lately it was only at the larger extremity that I have been able to distinguish an indication of an orifice; and this is situated, in many specimens, in the centre of a transverse, bilabiate, linear mouth.

The anterior third of the alimentary canal is more even than the remaining part, which presents a sacculated appearance; in this respect, the *Trichina* resembles the newly excluded young of *Ascarides* and *Strongyli*. A small rounded cluster of granules of a darker or more opaque nature than the rest of the body is situated about one-fifth the length of the animal from the larger or anterior extremity, and extends about half-way across the body.

The worm has no organic connexion with the cyst; sometimes two *Trichinæ*, rarely three, occur in the same cyst.

The Medina or Guinea-worm (*Filaria medinensis*, Gmel.) is developed in the subcutaneous cellular texture, generally in the lower extremities. The Trichocephalus is characterised by an orbicular mouth, but differs from it in the capillary tenuity of the anterior part of the body, and in the form of the sheath or preputial covering of the male spiculum. The species in question, the *Trichocephalus dispar* Rud., is of small size, and the male is rather less than the female. It occurs most commonly in the cæcum and colon, more rarely in the small intestines. Occasionally it is found loose in the abdominal cavity, having perforated the coats of the intestine. The capillary portion of this species makes about two-thirds of its entire length; it is transversely striated, and contains a straight intestinal canal; the head is acute, with a small simple terminal mouth. The thick part of the body is spirally convoluted on the same plane, and exhibits more plainly the dilated intestine; it terminates in an obtuse anal extremity, from the inner side of which project the intromittent spiculum and its sheath.

The species called *Spiroptera hominis* was founded by Rudolphi on some small nematoid worms expelled, with many larger elongated bodies of a solid texture, and with granular corpuscles, like ova, from the urinary bladder of a woman, whose case has been described by Mr. Lawrence in the Medico-Chirurgical Transactions.

The most formidable, but, happily, the rarest of the Nematoid parasites of man, called *Strongylus gigas*, also infests the urinary system, but is developed in the kidney, where it has attained the length of three feet, with a diameter of half an inch; occasioning suppuration and destructive absorption of that important glandular organ.

The male *Strongylus gigas* is less than the female, and is slightly attenuated at both extremities. The head is obtuse, the mouth orbicular, and surrounded by six hemispherical papillæ; the body is slightly marked with circular striæ, and with two longitudinal impressions; the tail is incurved in the male, and terminated by a dilated pouch or *bursa*, from the base of which the single intromittent spiculum projects. In the female the caudal extremity is less attenuated and straighter, with the anus a little below the apex; the vulva is situated at a short distance from the anterior extremity.

The most common intestinal worms of the present order are the *Ascaris Lumbricoides*, or round gut-worm of the small intestines, and the *Ascaris* or *Oxyurus vermicularis*, a small worm noticed by Hippocrates under the name of ασκαρις, and claiming the attention of all physicians since his time, as one of the most troublesome parasites of children, and occasionally of adults; in both of whom it infests the larger intestines, especially the rectum. The size of the male *Ascaris vermicularis* is two or three lines, that of the female is five lines.

The generative organs of the Cœlelmintha are more simple than in androgynous *Sterelmintha*, or even than in the diœcious *Echinorhynchi*; yet they are adapted for the production of a surprising number of fertile ova. In the *Linguatula* the organs of both sexes, and especicily of the female, are more complex than in the *Nematoidea*: I shall, however, briefly notice them before proceeding to demonstrate the parts of generation in the human parasite.

The male *Linguatula*, as in other diœcious Entozoa, is much smaller than the female; the generative apparatus consists of two winding seminal tubes or testes, and a single vas deferens, which carries the semen from the testes by a very narrow tube, and afterwards grows wider. It communicates anteriorly with two capillary processes, or *penes*, which are connected together at their origin by a cordiform glandular body, representing a prostate or vesicula seminalis. The external orifices of the male apparatus, according to Miram, are two in number, and

are situated on the dorsal aspect of the body just behind the head. Diesing, however, describes the male *Pentastoma* as having only a single penis, which protrudes just behind or below the oral aperture.

The female generative organs of the *Linguatula tænioides* present a structure in some respects analogous to that of the *Distoma perlatum*. The ovary is a part distinct from the tubular oviduct, and is attached to the integument or parietes of the body, extending down the middle of the dorsal aspect. It consists of a thin stratum of minute granules, clustered in a ramified form to minute white tubes, which converge and ultimately unite to form two oviducts. These tubes proceed from the anterior extremity of the ovary, diverge, pass on each side of the alimentary canal, and unite beneath the origins of the nerves of the body, so as to surround the œsophagus and these nerves as in a loop. The single tube formed by the union of the two oviducts above described, descends, winding round the alimentary canal in numerous coils, and terminates at the anal extremity of the body. The single oviduct, besides receiving the ova from the two tubes, communicates at its commencement with two elongated pyriform sacs, which receive from the male, *in coitu*, the semen, and convey it into the oviduct, with the addition of a mucous opaque secretion.

The spermatozoa of the Linguatula present the ordinary capillary or linear figure, with a slightly enlarged cephalic end.

The male organs in the Nematoidea consist of a single and simple, slender, elongated tube or testis, under its most elementary form, a seminal reservoir, and an intromittent organ, consisting of a single or double spiculum and its prepuce, or bursa.

The spiculum is simple in the genus *Filaria*. According to the observations of Dr. Leblond, the male-duct in the *Filaria papillosa* terminates at the anterior extremity of the body, close to the mouth. From this aperture the slender duct, after a sligh contortion, is continued straight down the body to a dilated elongated sac, which represents the testis.

In the *Trichocephalus dispar* the testis, a single tortuous tubule, commences by a blind extremity near the rectum, passes forwards to a dilated semina receptacle at the anterior part of the thick portion of the body, from which it bends backwards nearly the whole length of the thick part, constricted at irregular intervals, and terminating in a narro straight canal, which is continued into the inverte pyramidal appendage, or bursa, attached to the hinder extremity of the body, from which the single spiculum projects.

In the *Strongylus gigas*, the bursa or sheath of the penis, terminates the posterior extremity of the body, and is a cutaneous production of a round, en larged, truncated form, with the spiculum projecting from its centre. In other species of *Strongylus*, as in the *Strong. inflexus*, the bursa penis i bifid, and the intromittent organ is double. In the *Strongylus armatus* the bursa is quadrifid. The *Spiroptera* are distinguished by the aliform membranous caudal appendage in the male.

In the *Ascaris lumbricoides* the penis projects from the anterior part of the anus in the form of a slender, conical, slightly curved process, at the extremity of which a minute pore may be observed with the aid of the microscope. The base of the penis communicates with a seminal reservoir, and is attached to several muscular fibres, destined for its retraction and protrusion; the reservoir is about an inch in length, and gradually enlarges as it advances forwards; the testis or seminal tube extends to the anterior third of the body, forming numerous convolutions or loops about the intestine; its attenuated cæcal extremity adheres closely to the dorsal wall of the abdomen. The total length of the seminal tube is about three feet. The essential part of the fluid consists of nucleated cells, which, in the *Ascaris lumbricoides*, present an irregular, triangular, sub-compressed form. In the *Strongylus* they are subspherical, with a clear nucleus, which developes itself into a short rigid appendage; the body being formed by the persistent membrane of the spermatoon; but undergo, according to Dr. Bagge, a marked change of form when introduced into water; they then become elongated, and assume a wedge-shape.

Reichert has given good figures of the spermatozoa of the *Strongylus auricularis* and *Ascaris acuminata* in "Müller's Archives" for 1837.

From the examples which have been adduced of different genera of the Nematoidea, we may perceive that although there are many varieties of structure in the copulative part of the male generative apparatus, the essential or secerning portion uniformly consists of a single tube. A like uniformity of structure does not obtain in the essential parts of the female organs: in a few instances the ovary is single, corresponding to the testis in the male, but in the greater number of the nematoid worms it consists of two filamentary tubes.

The *Strongylus gigas* is an example of the more simple structure above alluded to. The single ovary commences by an obtuse blind extremity close to the anal extremity of the body, and is firmly attached to the termination of the intestine; it passes first in a straight line towards the anterior extremity of the body, and, when arrived to within a short distance from the vulva, is again attached to the parietes of the body, and makes a sudden turn backwards; it then forms two long hoops about the middle of the body, and returns again forwards, suddenly dilating into an uterus, which is three inches in length, and from the anterior extremity of which a slender cylindrical tube or vagina, about an inch in length, is continued, which, after forming a small convolution, terminates in the vulva, at the distance of two inches from the anterior extremity of the body. In the *Trichocephalus dispar* the ovarium and uterus are continuations of one and the same single tube, which by its folds more or less conceals the intestines; the vulva is situated nearly at the junction of the filamentous with the thick part of the body.

The theory which had suggested itself to Rudolphi, of the correlation of a simple oviduct in the female with the spiculum simplex of the male, and of the double oviduct with a spiculum duplex, is disproved by the circumstance of the uteri and oviducts being double in the *Strongylus armatus* and in the *Ascaris lumbricoides* in the males, of which the penis is a single spiculum. In the *Strongylus inflexus*, which infests the bronchial tubes and pulmonary vessels of the porpesse, each of the two female tubular organ may be divided into ovary, oviduct, and uterus; th ovary is one inch in length, commences by a poin opposite the middle of the body, and, after slightly enlarging, abruptly contracts into a capillary duc about two lines in length, which may be termed the oviduct or Fallopian tube, and this opens into a dilated moniliform uterus three inches in length. Both tubes are remarkably short, presenting none of the convolutions characteristic of the oviducts o *Ascaris* and *Filaria*, but extend in a straight line (with the exception of the short-twisted capillary communication between the ovaria and uteri) to the vulva, which forms a slight projection below the curved anal extremity of the body.

The reason of this situation of the vulva seems to be the fixed condition of the head of this species of *Strongylus*. In both sexes, it is commonly imbedded so tightly in a condensed portion of the periphery of the lung, as to be with difficulty extracted; the anal extremity, on the contrary, hangs freely in the larger branches of the bronchi, where the coitus, in consequence of the above disposition of the female organs, may readily take place.

In the *Strongylus armatus*, the two oviducts terminate in a single dilated uterus, and the vulva is situated at the anterior extremity of the body, close to the mouth.

I find a similar situation of the vulva in a species of *Filaria*, about thirty inches in length, which infests the abdominal cavity of the *Rhea*, or American ostrich. The single portion of the genital tube continued from the vulva, is one inch and a quarter in length; it then divides, and the two oviducts, after forming several interlaced convolutions in the middle third of the body, separate; one extends to the anal, the other to the oral extremities of the body, where the capillary portions of the oviducts respectively commence.

In the *Ascaris vermicularis*, the vulva is situated about one fourth of the length of the body from the head.

In the *Ascaris lumbricoides* the female organs consist of a vulva, a vagina, and a uterus, which divides into two long tortuous oviducts, gradually diminishing to capillary tubes, which may be regarded as the ovaria. All these parts are remarkable in the recent animal for their extreme whiteness. The vulva is situated on the ventral surface of the body, at the junction of the anterior and middle thirds of the body, which is generally marked at that part by a slight constriction. The *vagina* is a slightly wavy canal five or six lines in length, which passes beneath the intestine, and dilates into the uterus. The division of this part soon takes place, and the cornua extend with an irregularly wavy course to near the posterior extremity of the body, gradually diminishing in size; they are then reflected forwards, and form numerous, and apparently inextricable coils about the two posterior thirds of the intestine.

In the *Nematoidea* the male individual is always smaller, and sometimes disproportionately so, than the female. At the season of reproduction the anal extremity of the male is attached to the vulva of the female, by the intromission of the single or double spiculum, and the adhesion of the surrounding tumid labia; and, as the vulva of the female is generally situated at a distance from either extremity of her body, the male has the appearance of a branch or young individual sent off by gemmation, but attached at an acute angle to the body of the female.

The evidence of the fertility of the compound cestoid Entozoa, was sufficiently marvellous: that which I have now to adduce, from a calculation made by Dr. Eschricht, in reference to the *Ascaris lumbricoides*, the commonest intestinal parasite of the human species, is scarcely less surprising. The ova are arranged in the ovarian and uterine tubes like the flowers of the plantago, around a central stem or rachis. There are fifty in each circle, that is to say, you might count fifty ova in every transverse section of the tube. Now the thickness of each ovum is 1·500th of a line, so that in the length of one line there are 500 wreaths of fifty eggs each, or 25,000 eggs! The length of each division or horn of the uterus is 16 feet, or 2,304 lines, which for the two horns gives a length of 4,608 lines. The eggs, however, gradually increase in size so as to attain the thickness of 1·60th of a line; we, therefore, have at the lower end of the horn 60 wreaths of ova, or 3,000 ova in the extent of one line. The average number through the whole of the extraordinary extent of the tube may be taken at 14,000 ova in each line, which gives *sixty-four millions* of ova in the mature female *Ascaris lumbricoides!*

The embryo is not developed within the body in this species; the ova may be discharged by millions, and most of them must, in large cities, be carried into streams of water. An extremely small proportion is ever likely to be again introduced into the alimentary canal of that species of animal which can afford it an appropriate habitat. The remainder o he germs doubtless serve as food to numerous mi nute inhabitants of the water; and the prolific Entozoa may thus serve these little creatures in the same relation as the fruitful *Cerealia* in the vegetable kingdom stand to higher animals, and minister less o the perpetuation of their own species than to the sustenance of man.

The oviparous Entozoa present, perhaps, the most favourable subjects for studying with the requisite attention the successive steps of that process by which the germinal vesicle and yolk become finally ransmuted into the young and active worm.

I described and showed diagrams of some of these hanges in the ova of the *Strongylus inflexus* in my ectures on Generation in 1840: and the subject has been carefully prosecuted by Professors Siebold and Kolliker, from observations made upon the ova of he *Strongylus auricularis* and the *Ascaris acuminata*, both of them viviparous species of *Nematoidea*. Siebold finds at the delicate blind extremities of the varia the germinal vesicles, which are at first few and scattered, but become more closely aggregated as

they descend along the tube; whilst the ovum is progressively enlarged, by the multiplication of the opaque granules of the germ-yolk around the essential vesicle: then the delicate, smooth, and polished membrana vitelli is acquired. Towards the fundus the germinal vesicle becomes obscured by the aggregation of the vitelline granules around it; and after impregnation, the vesicle bursts and pours its contents over those granules. At all events, it ceases to be visible as a clear central cell. The ovum is now apparently occupied by the opaque and minute vitelline granules, which become aggregated or condensed, so as to leave a clear narrow inter-space between the vitelline mass and the smooth outer membrane. The yolk would seem to have been affected by a general spasm, or by some attractive principle added to it, which draws all its parts towards a centre. In the centre of this mass, in fact, a clear nucleus presents itself, which is more minute than the primitive germinal vesicle.

In the ova of Nematoidea, many of which are viviparous, the embryo is developed by two different modifications of the diffusive process by multiplication of germ cells from the primary central one: in the one process the successive division or propagation of the germ-cells goes on independently of the yolk, which is absorbed, assimilated, and converted into the matter of such germ-cells. In the other the attractive force of the germ nuclei seems to be greater: and the whole yolk is divided by the first bipartition of the original germ cell, and is assembled around these divisions, as they successively arise. So that the process is described as a successive division of the yolk. The subdivisions of the yolk decrease in size as they augment in number, and the vitelline matter is at length, by the re-iterated processes of development, liquefaction, and assimilation of nucleated cells, sufficiently subdivided and refined, and each subdivision or cell, by the concomitant partition of the clear spermatic nucleus or hyaline, has become adequately vitalised or fertilised, so as to be capable of its further metamorphosis into the appropriate tissue of the embryo worm.

So far the process is essentially the same with that in all other ova up to the mammal, and without doubt in man. The materials for the future being are accumulated in a duly subdivided state, like the bricks or hewn stones collected for the builder to operate on, under the guidance of the architect.

The minutely subdivided mass is now observed to present a lateral indentation; and, as this deepens, it assumes the form of a short thick cylinder, bent upon itself. By the lengthening and attenuation of the cylindrical mass, the bend assumes the character of a coil; and now something like an integument, containing a fine granular tissue, may be discerned. Further elongation, attenuation, more complicated coiling, and a greater clearness of the tissues of the embryo worm make its character plainly manifest, and the alimentary canal can be distinguished from the integument, both having been formed by the subdivision and metamorphosis of the primitive cells. The young animal thus built up, now begins to move briskly within the egg-membrane, assimilates the remaining vitelline mass, and is soon strong enough to burst its prison, and commence its independent career of existence.

The Entozoa are hardly less remarkable for their tenacity of life and revival from a state of apparent death than the Infusoria, and the knowledge of this property is indispensable to a fair estimation of the chances of the re-introduction of the ova of Entozoa into the bodies of living animals. In no class of animals has the origin from equivocal generation been more strenuously contended for than in regard to the Entozoa. The great entozoologists Rudolphi and Bremser were advocates of this doctrine; and Bremser did not scruple to charge the Berlin Professor with a physiological heresy, when he ventured to account for the high organisation of certain Ligulæ infesting piscivorous birds, by the hypothesis that they had been developed from the lower grade which they previously exhibited in the cold-blooded fishes swallowed by the birds, through the stimulus of the heat and nutritious secretions of the more comfortable intestinal domicile to which they had thus been accidentally introduced.

The advocates for the equivocal generation of the Entozoa adduce the fact, that herbivorous mammals are not less subject to Entozoa than carnivorous ones; and how, they inquire, could the ova of Entozoa be preserved in the water that serves as the drink of such animals? Or how, having become dried in the air, could such ova afterwards resume the requisite vitality for embryonic development? We may admit that the ova of Entozoa could not, like the much more minute ova of Polygastria, remain suspended in the atmosphere, since they are specifically heavier than water; but, with respect to their powers of retaining dormant life, we have sufficient analogical evidence to reject the assumption that they soon fall into decomposition.

Mr. Bauer has recorded many experiments on the *Vibrio tritici*, or parasite of wheat, a minute worm possessing the essential organisation of the Nematoidea, not less remarkable in their results than those of Spallanzani on the Rotifer; the Vibriones were dried, and when re-moistened, after the lapse of four to seven years, they resumed their living and active state. Dr. Blainville states, that the *Filaria papillosa* revives from a similar state of torpidity produced by desiccation.

It has been proved that the mature Entozoa will resist the effects of destructive agents, as extremes of heat and cold, to a degree beyond the powers of endurance of the *Rotifera*, and which would be truly surprising were not the simplicity of the organisation of the Entozoa taken into account. A Nematoid worm has been seen to exhibit strong contortions—evident vital motions—after having been subjected above an hour to the temperature of boiling water, with a codfish which it infested; and, on the other hand, Rudolphi relates that the Entozoa of the genus *Capsularia*, which infests the herrings that are annually sent to Berlin, hard frozen and packed in ice, do, when thawed, manifest unequivocal signs of restored vitality. If, then, the fully developed and mature entozoa can resist such powerful extraneous causes of destruction, how much more must the ova possess the power of enduring such without losing their latent life.

Burdach, who has summed up the evidence at great length in favour of the equivocal generation of the Entozoa, adduces the example of the oviparous species as involving the limitation of the offspring to the lifetime of the individual which they themselves infest; but on this point Dr. Eschricht has well observed that the transmission of the living young of the *Strongylus inflexus* from one porpoise to another is readily explicable. This species of *Strongylus* lives in the bronchial tubes, with its head immersed in the substance of the lungs, and its tail extended into the larger branches of the trachea. The living young must naturally escape into the mouth, and, as porpoises are gregarious, the young worms would, by a short passage through the water, readily be introduced into the mouth of another porpoise, and so reach the trachea.

The young of most Entozoa are subject to metamorphoses. I have already alluded to those of the Cestoidea in which the head in all the species seems first to be provided with six hooks. Those of the Trematoda are the most astonishing, and the locomotive condition of the earlier phases of the *Distomata* evidently relate to the securing their entry into the animal's body, which they are destined to infest. Dr. Siebold has noticed the difference of form between the young of the Echinorhynchi and their viviparous parents; and this difference was so great in regard to the viviparous *Filaria medinensis*, that Dr. Jacobson was led to suppose its multitudinous progeny to be parasites of the parasite. Dr. Eschricht has observed, that the flesh of fishes in summer is often studded with small worms, which, in one instance, he ascertained to be *Echinorhynchi*; and he suggests whether it may not be the breeding-place of such species, and whether the *Trichina spiralis* may not belong to the same category. But how these embryos (if they be embryos) are diffused through the intermuscular cellular tissue, can only be known after long and laborious investigations; and nothing is more true than that a particular inquiry will be required for each particular species.

LECTURES ON FEVER.

BEING AN ATTEMPT TO DEVELOPE MORE DEFINITE VIEWS OF ITS NATURE AND TREATMENT, BY THE CONSIDERATION OF THE PHENOMENA, AS OBSERVED IN THE PRACTICE OF MEDICINE AND SURGERY; BEING IN CONTINUATION OF "MEDICINE AND SURGERY ONE INDUCTIVE SCIENCE."

By GEO. MACILWAIN, F.R.C.S., Author of the above-mentioned Work, "Unity of the Body," "Tumors," &c., &c., &c.

(Concluded from Vol. XIX., page 601.)

Lecture X.

Of Stimulants.—Of Medicine generally —Of the Prevention of Fever.—Of Contagion and Infection.—A Word on Quarantine.—Of Sanitary Measures: Drainage and Sewerage, &c., only a Class of Prophylactics.—Facilities must be afforded for air, exercise, amusements, and the improved habits of the people.—Ignorance the great difficulty.—Public Instruction.—Remarks on Cholera.

The next subject on which it was proposed to state the bearing of the views which I have endeavoured to set forth, was the prevention of fever; but we shall do that more conveniently presently, in connexion with the remarks on sanitary measures. In the mean time, we must advert briefly to one or two of the more difficult and exceptional points of treatment, which want of space or opportunity has prevented us from doing hitherto. The time, the manner, and the circumstances which may justify the employment of what are called stimulants, are points of considerable importance. By a practical man, it is easily enough determined by the bed-side, but very difficult to point it out on paper.

The circumstances under which stimulants appear to me justifiable in fever, may be resolved into three: First, where the force, *ab extra*, is of unusual intensity, and productive of sudden and great depression, as happens in some cases of peculiar forms of miasma; and in surgery, from unusually severe concussions, or other injury to important parts; as temporary measures. Secondly, during the treatment in fevers of a low type; that is to say, with subdued power, in which aromatics seem to aid the operation of medicine addressed to particular organs, in inducing the premier pas in secretion. And, thirdly, when the very efforts of various organs to which the subsidence of the fever, properly so called, may have been owing, have exhausted the powers of the economy. All these conditions require vigilance and discrimination; first, that where they are really present, stimulants may be commenced in time; and, secondly, that they may not be given unnecessarily, and in cases where the real thing required may be the excitement of a particular function. So far as I have seen, when the usual symptoms of debility set in,—as darkening tongue, small quick pulse, wandering, and so on,—even if the tongue be moist, though it may, indeed, not always be safe to give any stimulant in the decided sense of the term, it is often very safe and very proper to give it as if asking the question whether it be admissible; for, if it be so, it will be almost certainly advantageous. If stimulants be necessary, their administration, with *extreme caution in time*, will, I believe, often prevent the necessity of that less measured use of them which so often winds up the typhoid termination of fever in defeat. When organs indeed are free from structural disease, much may be done by stimulants, even in very desperate circumstances. When they are changed in structure, stimulants only hurry on the mischief. Cases, indeed, apparently of an exceptional character, occur, and I recollect one where a patient recovered under the use of stimuli, combined, it is true, with a successful excitation of the supposed primarily affected organ, (the liver,) whose body I had the opportunity of examining a year afterwards, and in whom changes of structure in the organ were found, a considerable portion of which, I think, could not have been of recent occurrence. The choice of stimulants must of course depend on circumstances. A little jelly, slightly charged with wine, is a convenient form for

(so to speak) asking the question. Aromatics, when they are sufficient, are perhaps better than alcohol in any form. In many cases, and in desperate circumstances, alcohol, in some form or other, may be our only resource; and I once, I believe, got a very fine young man through a fever, in which he was delirious and apparently sinking for three weeks, by wine administered wholly by injection; but in which, it is pertinent to our argument to observe, was always productive of relief co-incidently only with secretion apparently from the liver. On the whole, stimulants can hardly be guarded by too much caution. Many cases in surgery which are accompanied by fever, and which were formerly treated by free use of stimulants, either at their commencement or termination, are now constantly and most successfully managed without either. As we have departed from the mere symptomatology, we have learned better things, and much of that sudden depression which we were accustomed to stimulate, and that excitement which we used to bleed; now (unless it occur in some threatening intensity) we merely endeavour to rouse or moderate, by temporary means; and recognise in these conditions only the ordinary phases of that process by which, under trying circumstances, the economy disposes of injurious influences. I believe the treatment of fever, which usually falls under the care of physicians, has been equally improved in this respect. I need scarcely say, that, in all cases, the choice of the article and the dose, and the time of giving stimulants, will be influenced by the previous habits of the patients, whence, indeed, as I contend, the elements of determining the special treatment will always be directly or indirectly deducible.

MEDICINE.

I have no opportunity of going into the details of what particular medicines we should employ to act on the organ we desire to influence, their doses, combinations, &c. My own practice, in regard to medicine, is generally simple and definite. I prescribe an article, and in a dose that I think can be depended on; and if there is a disposition in any other organ to be affected by it, than that on which I intend it to act, I generally increase the dose, and combine it with a narcotic. I am not fond of indefinitely increasing the quantity of that which has been given already in a full dose without effect, but prefer changing the excitant for some other; but, in the adjustment of the dose, of course, the previous habits of the patient, whether natural or acquired, in regard to medicine of any particular kind, will be of great consequence.

I have, however, said so much in connexion with my remarks on tumors with relation to medicine in the treatment of organs, that I can hardly enlarge on the subject without repetition. Steadiness is the great thing in practice, whether in fever or any other case. A prompt circumspection should establish all the external favourable conditions, as quiet, temperature, ventilation, &c.; then, whatever medicine is given should be prescribed with definite object, in sufficient dose, and its effect watched and reasonably waited for; all that fidgetty desire to be continually doing *something* may please the ignorant, but it is as unsafe as it *is injudicious.*

In proceeding with the points yet remaining to be considered, and as introducing the subject,—the Prevention of Fever,—I would observe, that to some it may have appeared that we have not laid so much stress on the influence exerted by atmospheric agency in the causation of fever as its importance demands. This has not been my intention. I contend that, either atmospheric changes, or additions, or vitiated conditions of the body, proceeding from other causes, may *each* generate the elements of fever; but I have been desirous chiefly to impress the importance of that element represented by the state of the body, because it is that with which we have to deal, that which is most within our power, and, as medical men, most falling within our professional duties; and in regard to which practice seems most inert, indefinite, or defective. At present, we know comparatively little which is positive concerning the atmosphere in relation to the production of epidemics; but it seems probable that there are two conditions which render it insalubrious. The one, the positive addition of some new principle, or agent, such as many deleterious gases with which we are familiar; the other, an altered condition of the polarities, or molecular attraction, of the normal constituents of the atmosphere, such as would be expressed by saying there was a difference in its electrical condition.

It is quite certain, that there is a state of body, and a state of atmosphere, which are each capable of producing fever; that as ordinarily, in epidemics, they both contribute, so their disjunction will *generally* prevent fever; but that, as a certain degree of intensity in either may generate the force usually represented by the other, so if we would prevent fever we must secure immunity from both. This would be, according to our view, the actual conclusion from the premises; we shall see that it is equally the result of practical observation.

The facts are clear and indisputable, and can by no ingenuity be wrested to other than their obvious and direct conclusions. It is indisputable, that pure, good air, perfect ventilation, efficient drainage and sewerage, will indefinitely *diminish* the occurrence and *fatality* of fever, no matter whether there be an epidemic constitution of atmosphere or not. It is also indisputable, that a similar indefinite *diminution* of the occurrence and fatality of fever will also reward the observance of cleanliness and temperance, abstinence from the *abuse* of alcohol, in whatever shape, especially if sufficient food and exercise be added. But we have no evidence whatever that the observance of either one class of prophylactics will *absolutely* prevent fever. To obtain the maximum of good, we must observe both. Intemperance, and other vices, with sloth, dirt, &c., will produce a *certain number of* cases of fever, in spite of all the drainage, sewerage, and pure air in the world; and, on the contrary, all the exercise, cleanliness, and temperance will not protect *every one* from fever, who is obliged to reside in a foul atmosphere. The bearing of these facts on sanitary measures we shall presently consider; but it is necessary to say a few words on contagion, or infection,—in fact, on the communication of disease from one individual to another. In examining this question, as well as that of prevention of fever, if people would *only* have attended to the *facts*, much, as it appears to me, of the controversy might have been avoided. It is impossible to deny, that fever has been communicated from one individual to another, and one instance is as good as a million; and, on the other hand, it is equally certain that, in many instances, fevers, of various kinds, have *not* been communicated to individuals who have been exposed, in every conceivable way, to the emanations from the fevered persons.

In these facts there is nothing wonderful, or really discrepant; they each imply, that the state of the body is ordinarily a necessary *element* in the matter; but a too partial view appears to me to have been taken of the whole subject. We should begin by considering the simple fact, that the emanations of all bodies, healthy or diseased, are unwholesome to other bodies; whatever is exhaled from an organized being is not exhaled, or rejected, as an accidental result; but as necessary to the health of the individual. Even the odours so grateful to us, would be insalubrious, or poisonous, to the flowers which exhale them, were they restricted to such an atmosphere. The security which we enjoy under such circumstances results from some of the most beautiful provisions in nature; of these I need only point to the high temperature at which matters are usually exhaled from animal bodies,—the *carrier* power thus generated in the air by the currents consequent thereon,—the law of mutual repulsion, by which gaseous forms of matter become indefinitely diffused; the disagreeable odours, by which we are warned of the presence of respirable gases that are unwholesome; the irrespirable nature of others not odorous; the instinct observed in many animals with regard to their excrement, and so forth; and, lastly, the conditions consequent on the converse of all this experimentally illustrated when we interfere with such laws by artificial accumulations, or confinement of the matters in question.

But now comes another link in the chain of facts not sufficiently noticed, though surely well enough known, and of which my experience in the outvisiting Institutions of London has furnished abundant illustration; viz., that it does not by any means necessarily follow, that an atmosphere, rendered unhealthy by the diseased, shall any more produce the same *disease* in different persons, than in those who are contaminated by the exhalations of bodies as yet not labouring under disease. What I mean, for example, is, that hot and crowded rooms will sometimes produce indisposition, in different people, of different kinds; and an atmosphere, whether that of a fevered person, or air of foul drains, which shall be followed by fever in one person, may be followed in another by another form of indisposition; or, as we familiarly learn, by no indisposition at all. The varying results of the air of dissecting rooms are one of the many classes of facts in illustration of the foregoing.

So it is not necessary that the atmosphere of *fever* should necessarily produce *fever* in a person who may, nevertheless, be more or less injured by it. I have known cases where several individuals have been affected by the same injurious influence, and yet the *name* of the disease has been very different in all. In point of fact, a fever may be contagious, however paradoxical it may seem, which in the person affected may not produce the same form of disturbance in the economy. I know of no one source of malaria into which we can examine with anything like precision, in which we do not observe the very same class of facts. We always find evidences of insalubrity in all, but never in *any one form in all*, and this is only typical of what might be said in different degrees of the results of every injurious influence whatever. Now, all these considerations lead us again and again to the two forces which we have represented as the *ordinary* elements of fever, and to the possibility of either in extreme intensity generating the force usually represented by the other, and shows, I think, the fallacy of trying to argue for contagion *generally*, because examples of communication occur, or against contagion *generally*, because it may be absent in particular instances. It gives the notion of some abstraction which has no existence, the real thing being the *resultant* of different forces. In fact, it is to my mind very much the story of the cameleon over again — all are right and all are wrong. All fevers, under certain circumstances, are contagious, and it might, with equal truth, be affirmed, that under other circumstances no fever is so. The bearing, however, of this on quarantine, without absolutely proving that it can never do any good, places its claims as a preventive of fever very low in the scale of prophylactic measures. Still I would avoid the tendency which there appears to be to consider right the reverse of wrong, and to think there is no remedy for the faults and fallacies of the Quarantine Laws but a total abolition of the powers which they have conferred.

On the contrary, I think a power of prohibiting intercourse, under particular circumstances, should still exist and that, whilst the fallacy and commercial evils of quarantine were got rid of, we should not hastily throw aside a power which might, under special circumstances, be desirable. It would be no consolation if, on some occasion, *a disease*, were carried into a crowded, *unhealthy, seafaring neighbourhood*, that the ship or crew had no power of producing a *sweeping epidemic*. Sanitary regulations require comprehensive and sensible applications of *all* means of security; not necessarily the total abandonment, or exclusive adoption of *any*. I cannot leave the subject of contagion, and preventive measures, without paying a parting tribute to Dr. Hancock, whose book appears to me to have well nigh exhausted the arguments on the subject in relation to the plague; and as *mutatis mutandis* the same facts are applicable to other epidemics —the subject generally. But whilst I would concede, most respectfully, both to the contagionist and non-contagionist, the freest exercise of opinion on matters which really are in abeyance, I must protest against the right that any man has to hold an opinion that is logically untenable, until we have discovered some

fallacy in the science of reasoning, as yet unknown. For very much of the reasoning on this subject might be easily disposed of as being logically, that is, in fact, demonstrably false.

Now, the bearing of all this on the sanitary movements of Governments is highly practical. A very little consideration unfolds to us views at once simple and comprehensive; but it quickly exposes to us how much larger a thing the health of nations is than is likely to be embraced by those who look exclusively to any one part of this great question. It will be seen that our argument lays most stress on that element afforded by the condition of the body; because it is here that the special treatment of fever, it is here that, in the professional sense of the term, the Medical man is most required,—here where he is most needed,—here where he has most power. Had he the power, he would establish universal good drainage and sewerage, plentiful supply of light and air. He would realise the inestimable value of temperance, exercise, and a general obedience to the physical laws—he would show how often these are sacrificed to the desire of wealth, to an extent useless or mischievous, or to pursuits of equally measured or doubtful value; he would impress the sanitary value as well as moral excellence of well-regulated passions, of kind and benevolent feelings, and the inseparable connexion and harmony of those moral and physical laws identical in their source, alike beneficial in all their consequences, and alike necessary to the attainment of the maximum of health and longevity, as they are to rational pleasure or real happiness.

The Profession, as individuals, can do very little in initiating anything that is comprehensive and national; and the Government must have seen what may be expected from our corporate bodies. Strangely enough, however, they have in various matters consulted those in regard to the correction of evils who are most interested in their continuance. In sanitary matters they have gone rather differently to work, but still, as it appears to me, in a manner that does not convey an impression of a very comprehensive perceptivity as to the number and nature of the agenda; and which, therefore, suggests, that the advance of sanitary measures will be marked by delay and difficulty. It is essential that the true sources of disease should be fully understood, and not *one source* made too much the subject of legislation. Whatever good is thus obtained, being necessarily incomplete, will disappoint the too confiding, and apparently verify the predictions of the ignorant and disaffected. 2. The *knowledge* of the subject should be diffused by public instruction. These conditions premised, the establishment of efficient drainage, sewerage, ventilation, supplies of water, abolition of cess-pools, &c., would do some good, and then would come the *other no less urgent division* of the subject, the facilitating and elevating the amusements, and improving the habits of the people, which so many things now tend to degrade and demoralize. Governments cannot legislate people out of bad habits, in a direct sense; but they can place them under circumstances more or less favourable to the development of good ones.

They cannot legislate a man through four or five miles of brick and mortar into the pure air and the amusements of the country, but they can provide spaces nearer home. Restricted to a world of streets, if a man has a spare hour from labour, a breath of pure air and some amusement is the best prophylactic against disease of mind or body. If he have not this, or at least space for amusement of more social and rational sort, and is either excluded by education or habit from literary pleasures, he will become an animal, and a very bad sort of animal too; and, whether he is a Peer or a Peasant, he will be in principle the same: his pleasures will be animal. There may be more grossness in the one case than in the other; but, whether it be gin and beer, claret and Burgundy, pitch-and-toss or hazard, snuff or tobacco,—whatever the excitement may be, alimentary or sexual, the principles at work will be essentially the same. Now, the foregoing is too much the condition of the masses in large towns. It is when the intellect has no point of usefulness to which to direct its powers, when the exhilarating and innocent influences of air and exercise are withheld,—when there is no motive or subject for the exercise of social or rational pleasure,—when he *appears* idle because every employment that is pure and recreative is withheld, that Man becomes an animal, who, whether gregarious or solitary, is active only in sensuality, and reasoning only so far as reason can sharpen or multiply the gratification of animal propensities. Meanwhile, the facilities—nay, temptations—to vicious and hurtful pleasures are as numerous as those to rational and sanitary are scanty; whilst the habitations are ill-ventilated and confined, that whited sepulchre the gin shop is open, airy, and attractive. The *immediate* excitement of alcohol is as agreeable and alluring as its *future* effects are demoralizing and destructive. Its use, and almost by an invariable consequence its abuse, becomes universal. Hosts of capitalists, according to the amounts of their respective investments, live in the style of princes, and noblemen, or wealthy yeomen, on the profits of gin and beer; and the Government,—unconsciously as we would desire to think, but not less really,—trading on demands built on the moral and physical deterioration of the people, has its provident care lulled or obscured, and its conscience seared, in contemplating the consequent additions to the revenue. Well, then, a Government cannot prohibit people from the abuse of alcohol, but they can say, You may go and refresh yourselves by air and exercise, or by games, in spaces prepared for the purpose; and this is what I would insist on as necessary for sanitary, as well as higher, purposes —that we must attend to the amusements of the people. In the present state of the people, and the amount of population in these realms, it is not only a duty of a paternal Government, but one which a very few years will show cannot be safely compromised or neglected. Private individuals can do but little; and, even where time has been stolen from other pressing avocations, the difficulties of interesting those whose especial duty it is to attend to such matters, may and do, (without the sanction of Government,) become insuperable. I have myself spent a good deal of time in a suburban neighbourhood on this subject, where there are unusual facilities for the institution of amusement, and painful evidences of the necessity of it; but, although I offered to do it at my own expense, I failed to excite the smallest sympathy in the nobleman who is Lord of the Manor, and otherwise so placed that it would be fruitless to attempt anything of the kind without his sanction and assistance. The estimable nobleman (Lord Carlisle) who is now interesting himself on sanitary matters, will not only find, that provisions for improving the habits of the people will form a very necessary part in any attempt at efficient sanitary measures, but that the diffusion of practical information will also be essential.

There is no one source of difficulty so great, nothing which so indefinitely impedes the progress of useful legislation, as ignorance; and it is in vain to conceal that the most dense ignorance exists in regard to the nature and extent of the requisitions of an efficient sanitary code. I have had thirty years (twenty having been spent in active duties amongst the worst neighbourhoods, St. Luke's, Clerkenwell, St. Andrew's, Holborn, and Islington) abundant opportunities of observing the lower classes, and I have not been without ample means of comparing their information with that possessed by other classes of society.

The broad stratum of society represented by the middle classes is as usual the best informed, or I should say, perhaps, the least ignorant; but the absence of knowledge on such subjects is great and universal, and unquestionably greatest, amongst the very highest and very lowest classes.

Do not let it be supposed that I am unaware of the many splendid exceptions in both,—but I speak of the rule; and I would appeal to any medical man of practical experience for confirmation of the foregoing representations.

Now, as regards this ignorance in the masses, it is not only, as it seems to me, the duty, but the policy of the Government to enlighten it. Nothing would render legislation more facile. Nothing but dense ignorance can oppose the momentary inconvenience of individuals, ignorantly and grandiloquently styled an invasion of their rights, to measures calculated to improve the health of a Nation.

The facts on which the justice and necessity of a prompt summary jurisdiction in sanitary matters rest are established in numbers almost repelling perusal by their very accumulation.

With the machinery afforded by a willing and generous Medical Profession, diffusion of information would be easy. Competent persons might easily be found in every district, who might undertake, at seasonable times, and at reasonable remuneration, the task of public instruction.

This would somewhat increase the too scanty provision, and immeasurably the usefulness, of our Profession. The times, subjects, and, if necessary, the mode or order in which they were treated, might be dictated by a tribunal appointed for that purpose.

Besides the *reservation of spaces* being part of an efficient Building Act, special provisions should be made for particular trades which are more or less unhealthy; or without such special provisions destructive.

Sanitary measures being placed on a broad and comprehensive basis, then should come, as an appropriate superstructure, the regulation of the Medical Profession. The principles might be few and simple. The public should be supplied with men whose title to practice should contain the proof that they had been examined as to their qualification; and for the security of the public, not less than in justice to the Profession, all persons not so qualified should be prevented from practising. No public officer of any institution should be allowed who had not attained his post by the result of successful scientific competition. The highest functionaries in professional distinction, viz., those which regulated the examinations, conferred degrees, and so on, should have ceased to be competitors in practice, and should be liberally paid out of the public purse. In all preliminary investigations, care should be taken not to consult those, still less *those only* who were directly or indirectly interested in the maintenance of existing evils. The subject is one of great importance to the public and the Profession; but whilst there are all around us so many evidences of deficient information on the part of the public, and so much evidence as to how little the Government appear to know of the real position of many of the men on whose sentiments they appear to have relied, for myself I see little hope for the public or the Profession. To return to the application of our views; if correct, they must have important bearings on the treatment of epidemics generally, and on that with which we are now visited, viz., cholera. They would in fact recognise it as one form of injurious influence, on which application of the general principles would be modified only by the unusually depressing force *ab extra*. This they would endeavour to combat by restraining excessive actions in affected organs, powerfully exciting the skin, and by the administration of stimulants, with a boldness and promptitude modified by the immediate pressure, and with a *prudent regard* to the degree of excitement which might follow the immediate recovery from the depressing influence; after this, the indisposition, whether febrile or other, would be treated in different cases by equalising functions which might appear out of balance, on the principles before suggested, so that in different individuals different indications would present themselves. The diarrhœa would, on our principles, stand in different relations in different cases; ordinarily, it would probably fall under the category of compensating actions in relation to which, practically, the skin would be most commonly the primary organ, or the one next in approximation thereto. Not having seen anything of cholera, I am not presuming to sketch its treatment, I am only saying what the general nature of it would be in harmony with our views of the laws which regulate the resistance to injurious influences on the body.

So far as I have observed, there is nothing inconsistent in this with the little which has yet been found successful. I had intended to set forth the distinction, so far as it can be so called, which exists between fever and inflammation, but I must dismiss, for want of space, that like many other of the foregoing important subjects, with one or two remarks. It will then be readily seen, from all that has been said, that fever and inflammation differ merely in that they are different phases of interference with the law by which the body deals with injurious influences; and, that, according to the nature or extent of the injury, or the number, degree, or kind of interfering influences, the two may be entirely separate, or variously combined. In the chain of phenomena thus formed, of which fever would be one terminal link, the case of what is called healthy inflammation without fever, would represent the other, the latter being, however, as a *terminal* link essentially artificial, because disconnected from those, represented by injurious or disturbing influences, which are *disposed of by secretion*. I have thus endeavoured to sketch, and to sketch only what I believe to be true views of the important subject of fever, so far as one can do so in continuing a work of which it forms only one article.

It is some consolation to me, in reflecting on the want of opportunity of fully analyzing so large a subject so as to carry every proposition, as to its nature, to a real demonstration; that I hope to have so far succeeded in unfolding my views, as to render the examination of their validity easy, and capable of being tested by any bodymoderately informed, by the bedside. That views which allege the so-called mysterious disturbance to be merely another phase of that law with which we are already in part familiar—that fever is susceptible of being so analysed as that the real nature and dependence of it can be shown to result from definite and intelligible conditions of the economy—that they must necessarily simplify our practice, and give it what I may call a clear and intelligible object, and confer on it a clear and explicable polarity, if I may so speak, instead of a vague routine of mere ministry to symptoms—that all this should be at once admitted, is neither to be expected or scarcely to be desired. There must be, however correct the views may be, at first, wholesome distrust, doubt, difficulty. The minds of men are already occupied by numerous assumptions, which must be got rid of. We have a number of imaginary entities, deduced from hypothetical, or what is worse, partial views, represented by the terms, idiopathic, symptomatic, nervous; which not only hang like dense clouds before the light of truth, but greatly impede even the examination of it. The instructions of Lord Bacon, in my opinion, can alone help us through these obstacles; and I do not believe that we can use the mind for the discovery of truth after any other manner which is so certain of a successful issue. At present, the diffusion of knowledge is curiously enough most restricted, on subjects in which mankind are most interested. Necessity having forced on them the practice of them as *arts*, they have neglected them almost entirely as a *science*—I mean agriculture and physiology. In such conditions of society, epidemics must always be fearful visitations, yet nothing is clearer than that they own their practical virulence *chiefly* to removable causes. But this arrangement is not accidental; it is one which is not answered by a feeling of thankfulness, however sincere; Man must do his duty; and he cannot do this without cultivating the powers which have been given him for the improvement of his race and the exaltation of his nature. Then he may happily repose in certainty on Him without whose knowledge no sparrow falleth to the ground; then may he expect in fulness to enjoy that protection of which his assurance as a Christian is so secure; but which, in some form of instinctive impulse or resting hope must have been present in men who, however less favoured, were still permitted to write—

Lecturer on Chemistry at the Medical College of the London Hospital.

LECTURE III.

A consideration of the influence which the license of counsel has on the development of crime.—The inconsistent conduct of the advocate in a Court of Justice.—Dickens's exposition thereof.—Fox's comments.—Influence which such conduct has on the moral feelings of the lawyer himself, as well as on the character of his profession, and the development of crime.—Scenes of the criminal court.—Origin of all this.—Mr. Forsyth's Hortensius; his defence of counsel.—Mode in which the depraved literature of the day affects an increase of crime; its pernicious influence on the public morals.—Popularity of every species of felon-literature; remarks by the Editor of the "Medical Gazette" thereon.—Objects of the preceding remarks.—Mode in which our inquiries are to be conducted.—Proper objects of the course.

GENTLEMEN,—At the conclusion of the last lecture we were about to consider what influence the unbridled conduct of the forensic advocate has on the development of crime. And I think that most persons will be ready to admit, that the license which is permitted to counsel in courts of law has a very injurious, not to say demoralizing tendency; for all who are conversant with the practice of such courts are aware, that the lawyer is never content with the performance of what may be termed his legitimate duty,—that is, the duty of *fairly* sifting evidence; but, taking advantage of his position near the Judge, and of his conversance with the intricacies of the forum, he strives, under the plea of eliciting truth, to browbeat, to intimidate, and finally to confuse the upright witness. Failing somewhat in this, for he is never quite unsuccessful, he hesitates not to appeal to the most irrelevant matters, as, for example, to attack the reputation of the deponent, to question his motives, to disparage his judgment, and, in fine, to adopt any course, whether it be legal or illegal, honest or dishonest, so that he may have a further chance of breaking down all that is opposed to the interests of his client.

Well enough have many of our popular writers deemed it to be necessary to expose and censure so gross and improper a condition of things. Even Dickens, with all his humour and levity, has more than once become serious upon this important subject, and has given us some very graphic descriptions of the inconsistencies of a lawyer's conduct. Need I remind you of his Mr. Serjeant Buzfuz—a too common character? or of what he tells us in the story from "Master Humphrey's Clock," where he says, that the advocate who was against poor honest Kit, and who had to speak first, was in dreadful good spirits; for he had, in the last trial, very nearly procured the acquittal of a young gentleman who had had the misfortune to murder his father. "He spoke up, you may be sure, telling the jury, that, if they acquitted *this* prisoner, they must expect to suffer no less pangs and agonies, than he had told the other jury they would certainly undergo if they convicted *that* one."

Another eloquent writer in commenting on this subject, says, "That which should be the pure, simple administration of justice—the balance of equity held between man and man—becomes, instead, a trade, where the vilest falsehoods are promulgated by the tongue of the hired advocate; where truth and falsehood are out of the question; where the palm of skill, the reward of merit, the highest honour, are given to him who can most triumphantly carry through the worst cause; where calumny and opprobrium are ready to be cast upon those to whom reverence is due, and where aspersions are always at hand for innocence and virtue. These, and such as these, are thought to be good, sound, lawyer-like proceedings; because the law, like the press, is deemed by some to be a trade—a sordid trade—instead of being, as it ought to be, the protector of the helpless, the redresser of injuries, the vindicator of the rights of our fellow-creatures."

This, gentlemen, is the language of one whose conversance with the effects of such practices upon society is very great—one whose well-known voice has often been heard in the defence of right, as well as in the condemnation of wrong; and many too there are who will readily join with him in the censure which is here so forcibly urged against the conduct of the "hired advocate," believing that the opprobrium which now rests upon the bar has been brought there by the free and unscrupulous conduct of its members—a conduct which no circumstance can make venial, and which no fee can ever requite; for it degrades the moral condition of him who uses it, as much as it does, the character of the profession to which it peculiarly belongs.

Truly, says a contemporary, the very doubtful question of obligation to exercise, for a fee, all one's faculties, alike to defeat a just, or to carry an iniquitous cause, is a sore trial to the ingenuous mind and clean soul. To examine a witness, whom you know to be perjuring himself; and to baffle the attempts of opponents who are endeavouring to extract the truth, is but strange fencing with morality; and when such conduct is confirmed by much practice, or by the experience of use, it has a tendency, to say the least of it, to blind the judgment, to corrupt the finest feelings, and to harden the purest heart. But, in my opinion, it does more than this; it weakens the barriers which have been raised against crime, and so tends to destroy some of the best elements of our social system.

If, gentlemen, I felt, that in order to give strength to these remarks, it was necessary for me to refer to the procedures of actual legal practice, I should do so, by recounting some of the scenes which are daily exhibited in one or other of the criminal courts of this kingdom,—scenes of counsel striving to obtain the management of the very worst of cases, and exerting themselves to the utmost in the defence of the very worst of criminals—scenes of subtlety, intrigue, and low cunning, such as could not be tolerated in any grade of society except the legal one—scenes of forensic display, in which every manly and honourable feeling are unhesitatingly sacrificed; in which there is a wanton perversion of truth, of law, of justice, and, in fact, of every good principle which does or can oppose itself to that for which the advocate is labouring, namely, the acquittal of an atrocious villain. Such an advocate must identify himself, more or less, with the being whom he defends; for it is impossible for him to practise his calling with that success which is so necessary to his pseudo-popularity, without his doing so; and, doing so, he can have no care, either for the intentions of the law, the dignity of his profession, or the common interests of society; but, being actuated by one solitary and bad principle—the love of gain—he toils on regardless of all the better feelings of human nature, making the law, as Mr. Warren justly says, not a blessing, but a curse, inasmuch as, through him, it offers a shield to the guilty, and becomes the detestable instrument of meanness, trickery, and oppression.

All this has arisen out of a privilege which has been most graciously accorded to the accused, viz., that he may have the benefit of counsel to advise, and of advocates to defend. So great a privilege has been extended to him simply with the view that his interests shall be fairly considered, and that law and justice shall be rightly administered to him. It was never intended that, through the exercise of such a prerogative, the ends of justice should be perverted, or that a blustering and unprincipled advocate should have the opportunity of making a ruthless attack upon the character and feelings of every witness whose testimony happened to be opposed to the interests of his client, and that client, too, in most cases, an acknowledged and atrocious scoundrel. Where, let me ask, is the person who has not at some time or other perceived, or, I may say, felt, the cruelty of such barbarous attacks? and who, having witnessed them, has not writhed in agony, and prayed that the judge would intercede

his authority so as to screen the defenceless victim from the merciless attacks of his assailants? I cannot perceive that there is any merit even in the successful issue of such proceedings, for the advocate occupies a position which detracts from any pretension either to bravery or to skill. In ninety-nine cases out of every hundred the lawyer is beyond the reach of danger, his assaults being directed against a weak and disordered adversary, one who is altogether unpractised in the weapons of his opponent; besides this, to quote from a contemporary, the advocate of the criminal is, generally a perfect master of the rules of the tournay, and has every advantage on his side, for his brief is conceal'd armour, and his "instructions" are a protection strong as the shield of Ajax.

Such an anomaly as the successful opposition of law to justice, or of truth to falsehood, ought not to exist, and all good men will, I am sure, admit that it cannot be too soon or too peremptorily put an end to; for who can have a doubt concerning the mischievous tendency of it, or who can question the great influence which it has in promoting the evil courses of the criminal.

Here, however, we ought to state that the liberty of speech and gross license which are too often indulged in by almost every member of the Law, have been somewhat checked, and perhaps in part reformed by some of our judges; but still we may say to them, even in the emphatic words of Hamlet, "O! reform it altogether, and let those who play your clowns speak no more than is set down for them."

In connexion with this subject I may, perhaps, be allowed to remark, that the opinion which I have here expressed concerning the conduct of barristers is not an uncommon one; on the contrary, it is the opinion which is very generally entertained by those who are at all acquainted with the practices of our criminal courts. Even the members of the bar are aware of this, and many efforts have been made by them, in order to show that the conduct of counsel is not only excusable, but necessary. One very ingenious defence has recently been published by Mr. Forsyth, but although I have carefully perused it, I cannot perceive that he has in any way supported his position; on the contrary, if we do away with his special pleading concerning the non-existence of this license, his arguments tend rather to condemn the system than to support it; for he says, "Such a license all right-thinking men must repudiate, and it tends only to the dishonour of a noble calling to represent it as requiring and justifying the use of trickery and falsehood. The principle is as clear as noon-day, that no man ought to do for another what that other cannot, without moral turpitude, do for himself. The advocate stands before the tribunal to plead the cause and represent the person of his client, *ulimur enim fictione personarum, et velut ore alieno loquimur*; but he cannot possibly, by virtue of his agency, acquire rights greater than are possessed by his principal. He may not assert that which he knows to be a lie. He may not connive at, much less attempt to substantiate, a fraud. He may not avail himself of the wretched sophistry of Paley, and say that there are falsehoods which are not lies; that is, which are not criminal. . . . In fine, every man is under an obligation to speak the truth if he speaks at all, and virtually promises to do so every time that he opens his lips." So, again, it must be admitted that "success in such a conflict has no ennobling feature, and happily mankind are so constituted as to value the heart more than the head, and withhold approbation from those whose powers of argument are better than their principles."

The last cause to which I shall allude, as having an influence on the crime of secret poisoning, *is the ill condition of the literature of the country*. No one can, I am sure, question the demoralizing tendency of a great portion of our modern romance. Its influence may be perceived in every grade of society, by its affecting the commonest, as well as the worst, of human passions, leading the ignorant and ill-disposed to be lieve, that crime, when it is well performed and well sustained, is commendable and heroic. Look, for example, at the pernicious influence of that style of literature which pertains to the new French school, and see how eagerly the multitude seek after the productions of such writers as Eugene Sue, Dumas, &c.; not to mention the names of some of our own countrymen who have followed in the same path, and who appear to pant after the same kind of pseudo-popularity. Ask at any public library, whether the stories of Jack Sheppard, Lucretia, Saint Croix, Brinvilliers, the Medecis, the Wandering Jew, the Mysteries of Paris, of London, &c., are not more sought after than any other writings of the day; and bethink you what must be the influence of such productions upon the course of the immoral. "We do not hesitate to declare," says the editor of the *Medical Gazette*, in a leading article for January the 15th, 1847, "that the fictitious literature of France and England has been mainly instrumental in producing the recent increase of the crime of poisoning in this country;" and he goes on to remark, that a large proportion of modern novels may be regarded as convenient hand-books of poisoning, for the guidance and instruction of the public. In every page are detailed the means whereby secret murder has been successfully perpetrated, with suggestions on the cautions to be pursued by future experimenters upon the lives of others, in order to avoid detection. Within the last twelve months three popular romances have been published in the English language, in which Cæsar Borgia, the prince of poisoners in the 15th century, has figured as a principal character. The fictitious histories of the Marchioness of Brinvilliers and Madame Laffarge, have lately vied with each other in exciting the prurient imaginations of the patrons of felon-literature; and the names of the "*Aquetta de Napoli*," and of the "*Manna of Saint Nicholas*," are now as familiar to the public ear, as were formerly those of the "*spirit of Mindererus*," or the "*Eau Medicinale*." It is, in fact, impossible to determine the extent of evil which is sure to be produced by the diffusion of this kind of literature; though we can readily imagine that it is among the secret sources of the very worst of crimes. Moreover, it must be evident, that the publication of such works of fiction has not only to do with the moral degeneration of the people, but it must also disgrace the history of the country, by exhibiting the depraved condition of the public mind, and the impotency or unconcern of the Government in all affairs which relate to the turpitude of the people. Well has a recent writer observed, in his comments on the character of our modern literature, that posterity will dig up from merited oblivion these monsters of iniquity, and regard them with a feeling of the geologist, who scans his uncouth vestiges of hideous creatures with mingled horror and surprise, thanking God that he did not live in that unhealthy and monstrous state of the world which fostered such things into form and animation.

Here, however, I must leave this subject: and, in doing so, I must offer to your consideration, as an apology for having wandered so far from the main object of these lectures, the importance of the matter with which we have been engaged, and the necessity which truly exists for the exposure and removal of the many sources of crime, before we can expect to put an efficient check upon the frequent perpetration of it.

I have also been led to think, that, by recounting the scenes which are so commonly witnessed in the Courts of coroners, of magistrates, and of judges, you might be enabled to form a faint estimate of the difficulties with which you will have to contend when you appear as medical witnesses therein. At a future time I shall take an opportunity to define your duties more clearly, and to point out the manner in which you are to proceed in all cases of suspected poisoning.

As to the mode in which we shall conduct our experimental inquiries in this place, I have to state, that we shall be occupied in making a practical examination of the physical and chemical properties of the various poisons; that we shall commence with the mineral acids, and then proceed to the alkalies, to the poisonous earths and metals proper; and, lastly, to the consideration of the properties of those poisonous substances which are of vegetable or animal origin.

I have chosen this mode of pursuing the subject, because I believe that it will lead us very gradually from the consideration of the simpler poisons up to the study of the more complex; and, also, because I believe that the ordinary mode of discussing and examining poisons, as for example under the heads of irritants, acrids, narcotics, &c., is open to many serious objections, not the least of which is the fact, that no satisfactory classification, either of poisons or of drugs, has yet been constructed upon a physiological basis.

And with regard to the rule by which I have been guided in filling up our list of poisonous substances, I may say that I have not been directed by any strict or scholastic definition of a poison, but I have simply brought together those substances which are generally supposed to produce a hurtful effect upon the living animal body. And I hold myself excused, also, from entering into any detail concerning the nature and *modus operandi* of the several poisons; because the medical literature of this country has already furnished a sufficient amount of information upon these points. It will be understood, therefore, that the object of these Lectures and instructions is of a truly practical character, so that they have been entered upon, not with the view of furnishing an elaborate dissertation upon the poisons, but merely for the purpose of supplying a few deficiencies which are acknowledged to exist in all our works on Toxicology, viz., deficiencies with regard to the clear exposition of those chemical processes whereby the presence of a poisonous substance is to be recognised. I trust, also, that in the course of our inquiries into the subject we shall be enabled to fill up many gaps, and to clear away many discrepancies, which exist at the present time in the chemistry of these bodies. Towards the end of the course I propose that we shall enter upon the subject of chemical and physical antidotes, and that we shall inquire into the facts which relate to the normal existence of certain poisons in the animal fabric. Other questions of considerable importance will doubtless present themselves during the pursuit of our investigations, and I shall not fail to direct your attention to them and to discuss them fully in their proper places.

In our next Lecture we will commence the examination of the mineral acids.

MEDICAL SCHOOLS AND UNIVERSITY TOWNS OF GERMANY.

By Dr. BUSHNAN.

(Continued from page 5.)

THE OFFICIAL MEDICAL OFFICERS OF GERMANY.

Attached to the Ministry or Department of Public Instruction, under the name of "Supreme Medical Board"—*Wissenschaftliche Deputation*—is a body placed at the head of all the medical affairs of the kingdom, and with the exception of the President and Secretary, formed entirely of medical men. No person whatever can obtain authority to practise, unless he has submitted to the State-examination—*Staats-Examen*-conducted by this Board. Dating its foundation, from the year 1685, it has ruled supreme since that period, and with but few changes or alterations from its original cast. Two kinds of duties are specially attached to it; first, the conferring licences on those proposing to practise as physicians, surgeons, accoucheurs, or apothecaries; and, secondly, arbitrating between patients and their medical attendants,—their award, in these cases, possessing all the authority and weight of judicial decisions. Similar colleges were nominated in 1724 for the respective provinces. In 1808, the direction of medical affairs was associated with the department of the Minister of the Interior; and in the subsequent year, the Supreme Medical College—*Ober Collegium*

Medicum—was suppressed. Finally, after various changes, the statutes of 1815 and 1817 regulated the now existing hierarchy of the public medical officials.

In virtue of these regulations, a medical college —*medicinal collegium*—exists in the capital town of each province, over which the governor presides or, in his absence, the first councillor. The members are six in number, the president, two physicians, an accoucheur, apothecary, and veterinary surgeon.

Their duties are to give advice or counsel to the Provincial Medical Government on every question of medical police. They revise also the pharmaceutical tariffs, and form a Committee of Examination for licensing practitioners. They further sit in evidence on ambiguous cases of legal medicine, confirm or ratify medical certificates, direct the sanitary measures demanded during epidemic or epizootic diseases, and further embrace the examination of mineral waters. Finally, they periodically transmit reports on the general medical affairs of the province to the Supreme Medical Board at Berlin.

Subordinate to the Provincial Medical College are the *medicinal racthe*, or medical councillors of the districts, into which each province is subdivided, each of whom resides in the capital town of their district. Under these, again, there is placed the lowest grade of the medical functionaries, the Medical and Surgical Inspectors of Cantons—*Kreisphysici and Kreiswundaerzte*—who are to watch over the practitioners in their respective cantons, and in all cases of legal medicine communicate with the judicial authorities.

The hierarchy of the public medical officials in Prussia conforms thus, in its distribution, to the political divisions of the Kingdom. The point of centralization is the capital, where the Supreme Medical Board presides. Descending to the provinces, we find in each a Provincial Medical College. Ramifying from these we meet a Medical Councillor in each district, while the cantons, or ultimate political divisions of the country, acknowledge the authority of their "Medical and Surgical Inspectors," of which there is one in each, as also one in each district. There are about three or four districts in a province, and the number of cantons in each of these varies from fifteen to twenty-five.

All the Medical Officers receive their pay from the State. It varies, according to the rank and length of service, from 50*l.* to 500*l.*, which is about the salary of the members of the Central Board.

These public medical functionaries are a perfectly distinct class of men, and have no connexion whatever with the faculties associated together for the purpose of teaching medicine. They do not obtain their appointments by the *concours*, but they must submit to an examination which is specially intended for them. Whatever academical degrees or honours are conferred by the Medical Faculties, it is only from the State, through the medium of the supreme Medical Board, that the licence to practise is procured; and to grant the necessary license constitutes one of the most important functions of the officers, whose duties we have now described.

THE METHOD OR COURSE OF STUDIES IN THE PRUSSIAN UNIVERSITY—THEIR DURATION—THE HOSPITALS—EXAMINATIONS.

As a step iniatory to matriculation in any of the Faculties of Prussia, as well as of the other States of Germany, it is indispensable to show a certificate that the holder thereof has concluded his classical studies. When the student has matriculated, he is presented with a card, which presents a printed list of the different lectures which are to engage him during the progress of his studies.

The period which is necessary to complete the medical curriculum extends to four years, constituting what is technically named the *quadriennium academicum*. Each course lasts six months, the lectures being delivered at least three times weekly by the Professors. The scholastic year extends from the end of October to near the close of March; and from the beginning of May to the middle of September.

Strict and formal almost to a degree, as are the rules laid down, it is most singular that the students are under no compulsion whatever as regards the order in which they should engage in their different studies; so that a pupil of the first year may be found pursuing a course of pathology or clinical medicine. The proper method of study is certainly pointed out to them by appropriate professors; but their words are generally unheeded by the student. And further, to complete the absurdity, there are no examinations instituted during the progress of the lectures, so that the first two or three years of a university life is generally spent in idleness and dissipation. Hence in the fourth year, students anxiously hurry to regain their lost time, and in their anxiety to pass their examinations, get crammed with a heterogeneous mixture of facts and theories, which fortunately many of them, when they have gained the object of their ambition, as speedily forget, to renew their studies in sober earnestness. Not one in twenty, says Dr. Hoeffer, employs seriously the full period designed for the course of study.

The first year is usually spent in attending the lectures on Natural Philosophy, Chemistry, Botany, Mineralogy, Zoology, Logic, and Psychology. It is necessary that the student in medicine pass an examination in these separate branches of study before the Faculty of Philosophy to obtain the degree of Doctor. It is imperative, also, that this examination should take place in the presence of the Dean of the Faculty of Medicine.

In the second and third years, the student usually is occupied in the study of Anatomy, Physiology, Pathology, Toxicology, and the History of Medicine. These are generally altogether of a theoretical character.

The dissecting-rooms have little attractions for students; and besides there is a paucity of *materiel*, in consequence of popular prejudice running high in Germany on that matter.

The fourth year is devoted usually to the study of midwifery, and clinical medicine.

Of the opportunities afforded for clinical education, that at La Charité, of Berlin, is the best known. But although this extensive Hospital contains nearly 1,000 beds, only 90 of these are set aside for the public medical and surgical clinical wards, and almost all the cases received there are of the acute type. The reason of the exclusion of the students from other wards is simply this, that the patients occupying them pay for their residence in the Hospital.

In the progress of his studies, the pupil at first merely walks the wards of the hospital, listening to the examinations of the patients by the physician or surgeon, and attending lectures. Students are then termed *auscultanten*. In the second division of their course of attendance in the hospital, they are termed *practicanten*, as then they receive and treat the patients themselves, visiting them every morning, and often twice a day, writing out their cases, and submitting them to the criticism of the clinical instructor; and, in the event of death, making the inspection, and reporting on the case.

It is not compulsory, however, on the pupils to expose themselves to all this turmoil, as it is only those who put their name down in a register for the purpose who enjoy the advantages of personal clinical instruction. In the surgical department of La Charité, the student *practicans* examines the patient under the eye of the surgeon, delivers his diagnosis, and gives him his assistance in the operating theatre. His functions then cease, for he is not entrusted with the after-treatment, nor does he again see the patient.

Commonly the student *practicans* does not treat more than three or four patients during each session. One year is the time given to Hospital attendance, the instances of two years being so employed are rare.

The examination for the degree of Doctor is a matter of mere form. There is both a written and an oral examination. A Latin dissertation is required, the subject of which the candidate may select himself, but it is more usually chosen by the Dean. Having defended this publicly, he is now acknowledged as *doctor medicinæ rité promotus*. This is, however, merely an honorary title, for it confers on him no authority whatever to practise. This is to be afterwards procured by submitting to the State-Examination, which alone confers the license on a practitioner, and is of a very formidable character.

The committee of the State Examination holds its sittings at Berlin. The regulations by which it is guided were laid down in 1825.

It examines for the purpose of granting a licence, PHYSICIANS, SURGEONS, AND APOTHECARIES.

Having obtained the doctorate from any of the faculties of medicine, the holders sometimes restrict themselves to the practice of medicine, or engage both in that of medicine and surgery. The examinations differ accordingly.

Of the searching nature of these State-Examinations, it is sufficient to observe, without entering into minute details, that they are of a most precise nature, and truly efficient. Fourteen days is the period usually allotted to the examination of candidates in medicine, though it may sometimes be prolonged to three weeks. In surgery it extends to fifteen days for those who desire to acquire the title of operator.

The examination for permission to exercise the art of apothecary, or pharmaceutist, is confined to chemistry, botany, pharmaceutic manipulations, toxicology, legal medicine, and chemical analysis. It will be seen from this, that the practice of medicine or of surgery is completely prohibited to the apothecary.

To fulfil the office of Medical Inspector of a Canton, the candidate has a certain number of dissertations proposed to him, three or six months in advance; he has to make a judicial investigation of a body according to the usual process; he must be well acquainted with the falsification of drugs; and, finally, he is interrogated by three examiners on all the departments of science which pertain to the public health.

These examinations are conducted at Berlin; but, they may also take place in the provinces, before a jury named for the purpose by the minister. To save expense to poor candidates, special juries have been appointed in the towns of Coblentz, Breslau, Kœnigsberg, and Greifswald.

(To be continued.)

UPON HÆMATURIA AND ITS DIAGNOSIS.

By ROBERT VENABLES, A.M. M.B. Oxon; Incep. Cand. Royal College of Physicians, London.

Were we to decide the presence of blood, or, indeed, of many of the abnormal principles occasionally present in the urine, from the general or special appearance of the excretion itself, or from the apparent characters of the deposits which subside, after the urine has been left quiescent for some hours, we should often be betrayed into serious error, as the following histories will serve to illustrate:—

I was consulted, a short time since, by a gentleman, aged about 60, in consequence of his having observed blood, as he supposed, upon several occasions, in the urine voided, more particularly, after taking exercise,—that is, after walking more than was his general custom. Nor was this suspicion confined to himself alone, as some others—and expert observers, too—adopted the same view. I obtained a specimen for examination; it presented the following characters:—

It was turbid, dark, and quite opaque. Upon standing for some hours, a dark red-looking sediment fell down to the bottom of the jar. The supernatant urine retained no particular colour, remained turbid, but allowed the light to pass through. Passed through the filter, it came through of a deep and bright amber colour, and perfectly transparent. No peculiar smell. Sp. gr. 1030. Reddened litmus paper.

What was retained on the filter, examined by the

microscope, presented a number of epithelial scales, somewhat coloured; some globules of mucus, and a few square tables of lithic acid.

The filtered urine, examined for albumen by heat, with both nitric acid, nitro-hydrochloric acid, and prussiate of potass, gave merely a haze, but no trace of this principle. Uric acid separated in very small quantity from the acidulated urine. Solution of sesquicarbonate of ammonia threw down a large quantity of prismatic double phosphate, and also some phosphate of lime.

A portion of the dark reddish sediment, placed under the microscope, was found to consist of very minute rhombs of uric acid (a) of rather a dark outline, agglutinated together, and intermixed with epithelium of a deep colour.

A portion collected from the filter, and ignited, left a residuum which resisted all further action of th heat, even the blow-pipe flame. This residuum mixed with charcoal, and ignited before the blow pipe flame, was not attracted by the magnet, and consequently, could not have contained any magneti iron. The residuum, after ignition, boiled wit nitro hydrochloric acid, filtered and diluted wit water, and treated with yellow prussiate of potass gave no appearance whatever of prussian blue. Nor did tincture of galls, or hydrosulphate of am monia, indicate even a trace of iron. Under thes circumstances, I felt warranted in denying th presence of *blood* in this urine.

I never met with urine of similar character bu once before, about three years since. It was specimen brought to me by a gentleman; it pre sented much the same characters as those just now detailed; nor could I satisfy myself, after a rigi examination similar to that pursued in the presen case, of the presence of blood. On stating this t the patient, he assured me, that his urine had been pronounced bloody by several gentlemen whom he had consulted. I found, too, that a specimen brought to me, upon a subsequent occasion, passed by the same gentleman, presented the most un equivocal evidence of containing blood, the presence of which was fully proved by both microscopical and chemical examination. I therefore concluded, that, by some accident or other, I had failed to detect the blood in the first specimen, and that I had deceived myself as to its nature.

But the circumstances and phenomena of the recent case were so precisely similar, that I determined to investigate the matter with the greatest possible care and attention. I therefore repeated the analysis three several times, and I was unable to discover, upon any one occasion, any evidence of the presence of blood—not even a trace.

Hæmaturia, however, of a most unequivocal and indisputable nature, supervening in the first case after a short interval, induced me, upon the present occasion, when stating to the patient that the urinary sediments, though peculiar, afforded no evidence of being blood, to apprise him that it might be the precursor of, and in all probability would be followed by urinary hæmorrhage, a prediction which, whether warranted or not by the circumstances, turned out to be true. The first specimen I received on the 20th June, and it was the fourth or fifth occasion upon which, after sharp exercise, the bloody-looking sediment appeared in the urine.(b)

On the 2nd July, I received a second specimen of the urine passed by the same gentleman, after active exercise in walking. This was darkish and opaque, but on standing let fall a dense, dark red looking mass, leaving the supernatant urine turbid, semi-opaque, and of rather a brightish red colour. It was nearly devoid of smell; sp. gr. 1030; reddened litmus paper, and abounded, as did the former specimen, in urea, and the earthy phosphates. The presence of blood in this urine was most fully proved by the following evidence:—

A portion of the sediment placed under the microscope clearly showed the blood discs. The urine thrown on the filter, though of the brightish red above described, came through of a light amber colour, without any appearance of red.

A small portion of the matter retained by the filter, collected, transferred to a slide, and placed under the microscope, showed the blood corpuscles, thus proving that the reddish colour of the supernatant urine depended upon the mechanical suspension or intermixture of the red particles.

A portion of the dark red sediment collected and ignited before the blow pipe, with charcoal, became magnetic, being strongly attracted by the magnet. Another portion ignited; the residue after ignition was boiled with nitro-hydro-chloric acid. The solution diluted with distilled water, and passed through the filter, gave, with the usual tests, distinct and unequivocal evidence of the presence of iron; for instance, with yellow prussiate of potass i formed Prussian blue; tincture of galls threw dow the black precipitate; and hydro-sulphate of am monia threw down sulphuret of iron; free sulphu being precipitated, when hydro-sulphuric acid alon was used.(a)

Assuming, from the above, that in the two cases the particulars of which have just been stated, that peculiar condition of the urine—*apparently* but no *really*, sanguineous—preceded actual hæmaturia it may be matter for future inquiry, whether such condition is necessarily a precursor of bloody urine r whether it be a precursor only of some particula form or forms? Then the question naturally arises what peculiar hæmorrhagic condition does it indicat as threatened? For myself, the opportunities o observation and for forming inferences have been too limited to enable me to offer anything plausible ven, much less satisfactory or conclusive. There is one result, however, of importance, the necessity o not being over-hasty in deciding the nature o urinary deposits, without chemically or otherwise determining their properties.

Urine containing blood is almost necessarily lbuminous; for we can hardly imagine the bloodiscs escaping without the serum; and it was the non-coagulability in the first specimen of the filtered urine, and its *coagulability* and reddish colour previous to filtration in the second, which led me to believe the first to be devoid of blood; and, in the second, to infer the presence of blood and the general sanguineous character of this urine.

Another question also presents here,—the most easy and the most ready means of deciding the sanguineous character of the urinary deposits, and of the urine itself? The elements f the blood may be arranged under the three llowing heads; viz., the serum, an albuminis fluid not spontaneously coagulable; the liquor sanguinis, a fibrinous fluid spontaneously coagulating, in consequence of the spontaneous solidification of the fibrine; and the hæmatine, constituting he red particles. The two first may occur in the rine, as has been frequently observed after certain febrile states of system, especially scarlatina, after hich coagulable urine often occurs as a sequela. But we can hardly consider any urine as bloody, unless the red particles of the blood be present; and many instances occur in which the urine, from its general *sensible* properties, would be pronounced bloody. The detection, therefore, of the red particles seem essential to be able to pronounce the urine really and unquestionably sanguineous. The coagulability of the urine by heat and certain re-agents, affords, in doubtful cases, but presumptive evidence; consequently, we must look to the hæmatosine as the only certain proof of the sanguineous nature of the urine.

The microscope is much relied on for the detection of the blood discs; but, as it is liable to certain fallacies, and in some instances wholly inapplicable, from changes in the blood discs themselves,—we cannot safely depend upon it. Chemistry offers the next, and probably the most unequivocal means of detecting hæmatine. M. Pariset proposes the following:—Boil and filter the urine, when brown coagulums of albumen and hæmatosine will be retained by the filter. Pour upon these a solution of potass; a greenish fluid will pass through, if hæmatosine were present. If hydrochloric acid be added to the filtered liquor, it will precipitate coagulums of white proteine. This, however, is liable to certain fallacies, which it would be foreign here to our purpose to discuss. It will be necessary to understand the principles of diagnostics in the previous detail, to state the chemical composition of hæmatosine. Mulder, from his analysis deduced the following formula for hæmatosine:—

$N_3 \; H_{22} \; C_{44} \; O_6 \; Fe_1$

The iron in hæmatosine is in the ratio of 6·64 or 6·66 per cent. As iron is an essential principle in the constitution of hæmatosine, it necessarily follows, that if blood be effused into the urine, we shall be able to discover some trace of iron; and this is the foundation of the pathological views enunciated in the preceding observations.

Various methods may be proposed for the detection of the iron; but perhaps the most simple consists in boiling the urine, and coagulating all the principles coagulable by a temperature of 212° Ft. It may next be filtered, and what is retained by the filter should be exposed for some time to a red heat in a platinum crucible, or one of Berlin ware. By this means all the organic matters, and other volatile principles, will be dissipated. The residue may then be mixed with charcoal or black fluid, and ignited before the blowpipe. The iron by these means will be reduced, and rendered magnetic, that is, attractable by the magnet. We thus determine the presence of a principle capable of being rendered attractable by the magnet.

If the ignited or reduced principle be now suspended in distilled water, and a current of chlorine passed through, a chloride of iron will be found in solution, which, on exposure to the air, will pass into sesquichloride.

The ignited mass will consist of oxide of iron mixed with certain fixed salts, as phosphates, &c. From these the iron may be separated by the magnet; but this manipulation will not be necessary.

As the transmission of chlorine may be difficult to some, every object may be attained by digesting the magnetic particles, or even the entire residue, in hydrochloric acid. A chloride of iron will be formed easily convertible into sesquichloride, by boiling with a small quantity of nitric acid. The sesquichloride of iron may be formed at once, by boiling with nitro-hydrochloric acid, prepared by mixing three parts of hydrochloric with one of nitric acid. The solution should be mixed with distilled water, and passed through the filter.

If the iron be in the state of protosalt, ammonia produces a white precipitate, which soon passes to bluish green. Yellow prussiate of potass, a precipitate, at first white, but which soon becomes blue. Hydrosulphuric acid has no action; but if, after passing through a current of the gas, ammonia be added, a black protosulphuret of iron precipitates. The most characteristic test is a solution of red prussiate of potass, which gives Prussian blue. This does not act on the per or sesquisalts.

If the iron be in the state of a persalt, ammonia throws down a brownish-red precipitate of hydrated sesquioxide; solution of yellow prussiate of potass immediately gives rise to the formation of Prussian blue. Sulphocyanide of potassium strikes a deep blood-red colour; but there is no precipitate. Tannin, or tincture of galls, gives the solution of iron a deep violet or black colour. A current of hydrosulphuric acid is attended with the separation of a

(a) I met with very minute rhombs of this sort upon several occasions. The first specimen I showed to Mr. Quekett, and we could not make out their nature for some time. By repeated examination, and getting some of them separated, the rhombic outline became evident. Agglutinated together in this way, and deposited upon the calculus, is, perhaps, the cause of the laminated structure of uric and calculi.

(b) It is remarkable feature, and a somewhat singular coincidence in the history of these two cases, that the urine passed in the morning, after rest, was perfectly clear and natural, and remained so till unusual or severe exercise caused a re appearance of the sediment and hæmorrhagic characters.

(a) It would be quite out of place here to detail minutely and at length the various processes and experiments, both positive and negative, by which the presence or absence of iron was either proved or inferred.

white precipitate, which is free sulphur. If to the filtered fluid ammonia be now added, the black sesquisulphuret of iron falls down. The presence of iron, even in the most minute quantity, may be thus determined; but, where the quantity is exceedingly minute, the evidence of its presence will not be immediate, and will probably require several hours for its complete development.

I have been diffuse in these observations, because I think the matter as important as it is interesting, more especially as relates to diagnostics. I have no doubt that many errors, and wrong notions, as to blood in the urine, have prevailed. In some the sensible characters so closely resemble those of bloody urine, that reliance upon them alone must lead to error. In the hope that these observations will lead to closer investigation, I have been induced to send them for publication in the *Medical Times*.

5, St. Vincent's Place, City-road,
11th July, 1849.

PROGRESS OF MEDICAL SCIENCE.

FRANCE.

As was to be expected towards the close of the epidemic, a few lingering cases of cholera still continue to appear from time to time, both in the city and in the hospitals. Occasionally, also, the mortality exhibits a slight increase; but, as it does not exceed eight or ten per day is hardly worth noticing. One of its latest victims has been M. Hemey, officer of the Legion of Honour, and Director of Salpetriere, who died on the 14th, although his attack dates more than six weeks back. A typhoid fever, of that low kind, which occasionally supervenes after cholera, was the cause of M. Hemey's death.

The Academy of Medicine has not yet produced its long-promised "Directions for the Treatment of Cholera," nor pronounced any decided opinion on the contagious nature of the malady. Our warm-blooded neighbours are marvellously slow in many respects.

MONOMANIA EROTICA.

One of the most curious cases of this kind on record came before the notice of the tribunals in the early part of the week. As it is almost unique, I shall relate it in detail.

François Bertrand, 25 years of age, was sergeant in the 74th regiment of the line, which he had joined as a volunteer in the year 1844. He is a young man of interesting appearance, extremely pale, and nothing in his countenance indicates the dreadful malady under which he labours. His answers are perfectly clear, and his previous conduct in the regiment had been such as to gain the approbation of his superiors, which led to his promotion from the ranks.

About three years ago, the Cemetery at Bleré, near Tours, was entered by some persons unknown, and the graves opened. The wife of the grave-digger thought she recognised one of the soldiers of the garrison, but no attention was paid to this circumstance, and the matter dropped. At a later period, similar violations of the tomb were repeatedly committed at Père la-Chaise, but the malefactor was sought in vain. Once, indeed, the watch discovered Serjeant Bertrand, in uniform, concealed in a freshly-opened grave; but he explained his presence in the cemetery, by a *rendez-vous* with his sweetheart, and was released.

The scene of violation was next transferred to Ivry, where the greatest consternation was excited amongst the rural population. A young girl, seven years of age, had been cut off rapidly by disease. According to the beautiful custom which prevails in France, she was placed in her bier, clothed in the finest of her white robes, and surrounded by her favourite playthings. On the following night her tomb was opened; the robe was torn into fragments, and the body mutilated. A sacrilegious hand had torn out the child's heart, and, strange to say, the ignorant peasantry attributed the misdeed to the infant's father. The most rigorous researches remained fruitless.

But it was in the Cemetery of Mount Parnassus, and after the dreadful days of June, 1848, that the violations alluded to became more frequent and horrifying. Almost every morning the guardians found the bodies of females, mutilated in the most disgusting manner, and cast about the remote paths of the burial-ground. Their redoubled exertions to detect the intruder remained, as heretofore, fruitless. Even the savage dogs, trained to guard the sanctuary, seemed to have forgotten their duty. Extraordinary measures were now had recourse to. A musket, loaded to the muzzle, was placed on a tomb opposite a part of the wall where some traces of scaling had been remarked, a wire, connecting the trigger with the portion of wall alluded to, was carefully arranged, and the men remained on watch in the neighbourhood. At midnight a dreadful explosion was heard, and when the guards rushed to the spot, they perceived a young man bounding, with a tiger's agility, over the tombs. In a few seconds he was at the foot of the wall, which is nine feet high, and disappeared on the other side; the guardians were unable to surmount the obstacle, they fired a shot or two at the intruder as he scaled the wall, and found some fragments of uniform on the ground, with traces of blood and footsteps—nothing more. The culprit had again escaped in a miraculous manner, and might have remained undetected but for a most curious chance. The event had occurred on the evening of the day which preceded the execution of Daix and Lahr for the assassination of General Brea. On the day of execution, the line of troops extended from the Barrière of Fontainebleau to the Cemetery of Mount Parnassus. As the grave-digger was hollowing out the grave destined for the assassins, he accidentally overheard some soldiers of the 74th relate how one of their sergeants had been cruelly wounded, in a mysterious manner, on the preceding night, and how he now lay at Val-de-Grace.

This led to the discovery of Bertrand, who ultimately confessed all to M. Marshal de Calvi, one of the surgeons of the hospital. Although the unhappy maniac had received several dangerous wounds in the chest and other parts of the body, from which fragments of lead and iron were extracted, he recovered, and was tried on the 10th ult.

A short note, which he had transmitted to M. Marshal, contains the essence of the case, and is worthy of record:—

"From the age of seven years (says the writer,) my parents remarked, that I was subject to a species of mental derangement. I frequently retired to the most solitary places, and there remained for hours, absorbed in myself. It was in February, 1847, that I was first seized with a kind of fury. I was walking with one of my comrades near the cemetery of Ivry, when I remarked that the grave-digger had left near the grave the several instruments which he employed in his work. I cannot describe the sensations I experienced at the sight. As soon as I could get rid of my companion, I returned to the grave-yard, disinterred the body, and mutilated it. I then placed the body in the grave; but, as I perceived some persons at the gate, I apprehended detection, and lay down for some time beside the dead body. On leaving the cemetery I was seized with a kind of fever, and remained for two hours in a complete state of lethargy. Two days afterwards I returned to the grave-yard, reopened the same grave with my hands, and again mutilated the body.

"On arriving at Paris, I thought that my unfortunate passion had ceased; but some of my friends engaged me to visit *Père le Chaise* with them. I returned in the evening, disinterred a body, and experienced a strange pleasure from tearing it into pieces. I retired in a state of mental derangement; but when my reason was restored, I felt such horror at what I had done, that I remained seven or eight months without returning to the cemetery. I never could induce myself to mutilate the body of a man; as for females, I experienced the greatest pleasure while cutting up their bodies into pieces."

On his examination, Bertrand confessed, that he had often opened, with his hands alone, ten to fifteen graves in the same night. When the dogs rushed on him, he used to remain immoveable for a few minutes: the animals became appeased, and allowed him to pass on. In his state of exaltation he used to climb the highest walls without knowing how. Thus, although he received five wounds in the body, and twenty-nine projectiles in various parts of his dress, from the discharge of the musket at Mont Parnasse, he was able to bound over a high wall which none of the guards could climb over.

In some interesting remarks on this strange case, made by M. Marshal before the court, he observed, that the monomania of Bertrand was simply "destructive" in the commencement. After a considerable lapse of time, it became "erotic" also; and this result or complication is familiar to medical men. Dr. Baudens, chief physician to Val-du-Grace, was likewise of opinion that the acts committed by Bertrand had been perpetrated under the influence of an irresistible monomania. The court, notwithstanding, condemned the prisoner to twelve months' imprisonment. A case somewhat similar to the above occurred, I may remark, many years ago, in the neighbourhood of Versailles. But there the maniac was an Anthropophagus. He disintered bodies merely for the pleasure of eating them: and his favourite morsel was the intestinal canal. One day he noticed a child of twelve years of age near a wood in which he lay concealed. To seize the child, drag him into the wood, and strangle him, was the work of an instant. He then sucked his victim's blood, and eat the heart. When questioned by the court, his excuse was, *Je ne l'ai pas mangé tout à fait.* "I did not eat him entirely." Such cases are, fortunately, rare even in the wide circle of human derangements.

SUICIDE BY A CHILD.

A remarkable case of this kind, illustrating an unusual degree of perversity on the part of a child nine years old, occurred recently at Dunkerque. The boy first threw himself under the wheels of an omnibus and was rescued with some difficulty by the passers-by. He next attempted suicide by throwing himself before a railway train, but his attempt was frustrated in like manner. Finally, having announced to his little comrades that he was resolved on dying because his parents beat him every day, the unhappy infant threw himself into the canal at Bergues and there perished. Since the Revolution of February we have had several examples of suicide committed by children of very tender age.

CHAMELINE—A NEW VACCINE MATTER.

Dr. Agnielli, Director of the Committee of Vaccination at Algiers, has found a new virus, which, like the vaccine, is protective against small-pox, which he proposes to call "Chameline," since, according to the statement of the Arabs, it is the product of an accidental eruption on the female of the camel; it resembles that of the cow. We should rather imagine it to be *the* virus transmitted through a different animal, and not a resemblance only; and, if there be anything accidental about it, it is the camel, and not the eruption which is so. However, Dr. Agnielli intends travelling with a caravan, in order to verify his conjectures.

M. de Falloux, Minister of Public Instruction, intends, it would appear, to remodel the medical code and give it a definitive character. As a preliminary, he has appointed a Medical Committee to report on the modifications desirable. It is composed of M. Berard, Dean of the Faculty; Orfila, Paul Dubois, Trousseau, Denouvilliers, Dubois (d'Amiens), Recamier, Malgaigne, Guerin, Bussy, and Lassiger.

Dr. Berryer Fontaine, Director of Public Health, has been dismissed, and is replaced by M. Liskenne, who formerly occupied the post of Inspector-General in the same service. Berryer-Fontaine was a Republican, and hence the cause of his disgrace.

GERMANY.

TRANSPLANTATION OF TESTICLES.

In Müller's Archives is a most interesting paper with this title, by Professor Berthold, of Gottingen:—

A series of comparative experiments were made

by him: he castrated six young cocks, of two and three months old, leaving the wattles, combs, and spurs untouched.

From two of them (*a* and *d*), he removed both testicles. Thenceforth they took on the nature of capons, fighting very seldom and feebly, and giving the well-known monotonous capon crow. Their combs and wattles were pale, and little developed, and the head remained small. About five months after, they were killed; a small scar occupied the place of each testicle, and the seminal duct had degenerated to a mere thread.

From two others (*b* and *c*), only one testicle was removed, the other left in the belly. In two others (*e* and *f*), both testicles were excised, but one belonging to *e* was transplanted into the belly of *f*, and, *vice versa*, one of its testicles transplanted into *e*; thrust amongst the bowels, and left there.

All four retained the characters of uncastrated fowls; they crowed lustily, frequently fought with each other, and with other young cocks, and exhibited the ordinary inclination for the hens. Their combs and wattles developed like those of others.

The cock *b* was killed two months after; its single testicle was of the ordinary place, but had hypertrophied, and, on section, a white fluid exuded, which contained cells, but no spermatozoa.

On the same day, the remaining three had their well developed comb, and wattles excised. The cock *e*, at the same time, was deprived of the remaining testicle; and *c* and *f* examined in the ordinary situation in vain for their transplanted organ.

The now fully castrated *b* never grew comb or wattles; it ceased to concern itself about the hens, and fought no more with its own sex. *C* and *f*, however, reproduced both comb and wattles, and preserved their ordinary chivalrous demeanour. They were killed six months after the transplantation. In *c*, the testicle was found behind the colon and between the ends of the cœca. In *f* it was nearer their middle, but otherwise in the same situation. They were of large size, and received large branches of the mesenteric vessels, which passed towards them, entered, and then took the ordinary course, in relation to their seminal tubes. On incising them, a normal seminal fluid exuded with the ordinary cells and spermatozoa.

The author concludes:—

1. That the testicles are transplantable, and reunite with living tissues after their union from the body, not only at their ordinary site, but in an abnormal situation.

2. Like the grafted tree, the organ on this new place, still preserves its specific properties, and secretes its specific fluid.

3. It is well known, that after division, a reunion of nerves restores sensation and movement. And it follows, from these experiments, that as the re-union could not have been one of those originally divided, there are no *specific* seminal nerves; that nerves only are requisite—a strong, nay, almost a fatal objection to the theory, that would constitute the sympathetic a *trophic* nerve, or nerve in itself specifically organized with reference to nutrition.

4. The consensual and antagonistic relations of the life of the individual and the species, seen from puberty to old age, are continued in spite of the separation of the testicles from their ordinary place and nerves, and their removal to another part of the body. These animals were, in all respects, veritable *males*. It would thence follow, that the *consent* in question results from the productive relation of the testicle; that is, through the operation of its secreted fluid immediately upon the blood, and through a corresponding operation of the blood upon the general organism. In this, no doubt, the nervous system takes an important part. These experiments are most interesting, and fully bear out the Author's deductions; but the first must be limited to the animals in question, or, at least, must not be hastily extended to higher organizations or older animals. This, however, in no degree impairs the physiological conclusions set forth by the Author.

Still, however, the real question that science perpetually asks with a sigh, concerning all secretions, is as undecided as ever. "Why does the testicle secrete semen?"—we can as little answer as ever. Nay, more, let us recollect an important and much more immediate step in the process is wanting,—the great agent is unknown.

For how, from these instances, can we determine whether the union of nerves did or did not precede the resumption of secretion? or, let us say, rather, in such young animals, the *perfection* of this process? Yet an answer to this question would be an important addition to our present knowledge.

PROGRESS OF PHYSICAL SCIENCE.

ROYAL GEOGRAPHICAL SOCIETY.

June 25.—Second paper read "On the City of Abila and the district called Abilene, near Mount Lebanon, and on a Latin inscription at the river Lycus, in the north of Syria," by John Hogg, M.A., Hon. Secretary. Mr. Lempriere, of the Temple, in October, 1843, travelling between Balbec and Damascus, found two Latin inscriptions cut in two tablets on the side of a mountain at the foot of which the present road passes to Suk. The first inscription, (No. 1,) which is very perfect, consists of six lines, and is thus translated:—"The Emperor Cæsar Marcus Aurelius Antoninus Augustus Armeniacus, and the Emperor Cæsar Aurelius Verus Augustus Armeniacus, restored the road broken away by the force of the river, the mountain being cut through by the authority of Julius Verus, the Legate of the Proprietors of the Province of Syria and their friend, at the expense of the inhabitants of Abilene." The second inscription, (No. 2) contained in a smaller tablet, is somewhat obscure, and perhaps imperfect, in its second line. Mr. J. Hogg proposed to interpret it in one of the three following ways:—"For the safety (1st) of the Emperor Aurelius Verus; or (2nd) of the Emperors Marcus Aurelius and Aurelius Verus; or (3rd) of the (two) Emperors and of Verus Lucius Maximus, Tribune of the 16th Legion, called Flavia Firma, who presided over the work, living performed this vow for him (or them) deservedly." This Lucius Maximus must clearly be the same person, who is named Tribune of the same legion, in two Greek inscriptions found in Syria, and published in Burckhardt's travels in that country. The tablets containing the two inscriptions were more than 100 feet above the road. The mountain itself has been evidently cut through, as the inscription No. 1 records it had; and traces of the old Roman road are still visible above the present road. This place must have been in the territory of the Abilene, of which the chief city was Abila. Ruins of some ancient town had been observed by the late Dr. E. Hogg, near Suk, some years ago, and which, in all probability, was the site of Abila, the Tetrarch of which district was Lysanias (Luke iii. 1). The author cited authorities to prove that that spot agrees perfectly with the Abilene of Lysanias in or near Mount Lebanon, or rather Antilebanon; and that the city of Abila, (of which name there were some other cities in Syria) might have stood at or near the position now occupied by Suk. The date of the inscription No. 1 was about A.D. 164, and of No 2 later. These two inscriptions, as far as Mr. Hogg can find, have never been published, or made known, though Mr. Bankes is said to have noticed some inscriptions near that place; but that which was the subject of the second part of the communication has been described in a tablet exactly like that in which the inscription No. 1 is engraved in the natural rock, on the side of the "Antoninian Way" leading to Beirut, just over the Dog River, Nahr el Kelb, the ancient Wolf River of Strabo. The time of the erection of this last monument, the author considers to have been between A.D. 175 and 177. Its inscription is also of much importance in a topographical view, for as No. 1 fixes the locality of Abilene; so this decides which of the rivers on the Syrian coast was the ancient Lycus.

University of London.—The number of candidates for matriculation this year was unusually large, amounting to 166.—*Globe.*

TO SUBSCRIBERS.

Subscribers in want of any of the back Numbers are recommended to complete their sets. Cases for binding the volumes, price 2s. each, are now ready for delivery; and Portfolios, for preserving the weekly Numbers, price 3s.

New Subscribers will oblige by forwarding their Names direct to the Office, 147, Strand, or to the News Agents or Booksellers. All Post-office Orders should be made payable to the Publishers, Wm. S. Orr and Co.

THE MEDICAL TIMES.

SATURDAY, JULY 21, 1849.

We have lately, on several occasions, advocated most strongly the paramount necessity of some arrangement being made, and that quickly, for insuring a provision in the decline of life to the members of the Medical Profession, and at the same time apportioning an annuity for their widows and orphans. The subject has been indeed forced on us, as well by the memoirs we have been honoured with from various quarters, urging the consideration of the matter as one of vital importance to the Profession at large, as also by the melancholy retrospect of our medical career, in which we discover so many blanks left by the premature deaths of our early professional friends, chiefly, we must say, through the effects of contagious diseases. It is, therefore, with much satisfaction, that we observe a disposition on the part of the Profession to adopt in earnest some plan that shall be competent to obviate the effects of the shafts of fate" which seem to fall more than usually heavy on the members of the sister Professions of Medicine and Surgery.

Efforts have been made, variously modified, at different times, and in various localities, to attain this end. The schemes, however, being local, and necessarily limited in their sphere, (an objection almost fatal to arrangements or associations with such an object in contemplation, as their strength virtually depends on the number of the assured), they have had, for the most part, but a temporary existence, never being fully consolidated nor arriving at any maturity. For this various reasons might be assigned, but these it is unnecessary to inquire into: we shall, therefore, briefly as possible give the heads, or a summary detail of a plan that has been recently proposed, adding a few words by way of comment.

The Association to which we allude has originated with Mr. Hawtayne, and bears the name of the Medical and Clerical Annuity, Superannuation, and Benevolent Society, being established pursuant to the Act of Parliament and 7 Wm. IV. c. xxxii. It is based on the Mutual principle, and comprehends Three Distinct Objects.

"First.—That of granting annuities to the widows and orphans of the members of the above Professions at their decease.

"Secondly.—Of providing a superannuation fund" (deferred annuity) "for such of its members as may be incapacitated from pursuing their avocations from age, infirmity, &c., and

who, at the same time, shall not possess other adequate means of subsistence.

"Thirdly,—The formation of a Benevolent Fund, from donations, subscriptions, or other contributions, its purpose being purely philanthropic, directed to the aidance of distressed members of the Association and their families."

As a feature altogether new in the formation of this Association, in the case of widows and children, they reject the common plan of giving one sum, *in cumulo*, at death, considering it preferable to adopt the method, or system, of Annual Payments, as securing to the annuitant a larger pecuniary return than can be effected by the plan in ordinary practice.

With regard to the Annuity Branch, it is proposed,.

"First.—That to constitute a member, a fee of Two Guineas be paid on entrance, with an annual premium of not less than 1*l.* 10s., and that, at the time of nomination, a small equitable sum be paid for disparity of age between the member assuring and that of his nominee, as regulated by Tables to be especially constructed for the Association."

"Secondly.—Each annuity to commence at 15*l.*, and to be increased by the addition of 1*l.* annually to 20*l.* as a maximum; but no annuity to be claimable until five years' premium shal have been paid, either annually, or in one sum at the option of the member.

"Thirdly.—That each member may be allowed to subscribe for six annuities, but not more than three annuities can be granted to one nominee.

"Fourthly.—Annuities to widows of members to cease on their re-marrying, and to daughters on their marriage; but, in either case, to accrue again in the event of widowhood.

"Fifthly.—Annuities, on a reduced scale of payment, may be secured to male orphans, but to cease to be payable on their attaining their majority."

Another, and we judge a most essential and peculiar feature in the Society, is the Benevolent Fund, designed to afford temporary relief under sickness, accident, or other unforeseen contingency, formed from donations or voluntary subscriptions, somewhat analogous to sick allowances. In this arrangement, we conceive, at once the peculiar strength and attraction of the proposed Institution must rest, as the contingencies which beset the Medical life are so great as render it more than usually precarious. The propositions connected therewith require mature and deliberate consideration, especially to avoid all imputation of an eleemosynary nature to the too sensitive minds of the Profession.

While, then, we award our meed of praise to the general plan and principle, there are one or two points at which we feel disposed to take exception—perhaps we do this in ignorance—but as philanthropy is to be held as the basis of the whole superstructure of the Institution, we conceive the more simple and uniform the rules, the less the number of exceptional classes, the more all the members range on a par, so much the public, we firmly are persuaded, will judge more favourably of the Institution. When once a member has entered, he ought not to become disqualified, unless voluntarily, whatever part of the globe he may migrate to. This, we think, applies particularly to the medical man; for, though it may be true that, in actual warfare, his is a thrice-tried life nevertheless, in Great Britain, we believe, his chance of life is not much different, if we take the average of all the other quarters of the globe. The less intricate, the better; the more simple the working of the machinery, the more confidence will the Medical world have in it, and the more liberally, by parity of reason, will the Benevolent Fund be countenanced by the public.

Again, we do not say that the Institution does so, for the tables have not yet been published; but we would propose that there be no fines, and the utmost facility of re-admission offered to all and sundry. The Society should not feed and get pampered on the miseries of its members; the rates being distinctly calculated to withstand all contingencies, no chance accumulation or profit should be permitted. With respect, also, to the practical working of the Society, we have our fears, that the more profitable branches of the undertaking would engross all the attention of the managers, and thus that the benevolent portion of the scheme would be dwarfed into insignificance. We feel assured that a benevolent fund will require the entire energies and devotion of a distinct Society to make it successful. On this ground, then, we should ask Mr. Daniel to consider well before he sacrifice his infant Society to the interests of a new Institution. We have understood that Mr. Daniel has, in a very liberal and unselfish spirit, entertained the desire to merge the two Institutions into one. The policy of this act in the present stage of the proceedings would be doubtful; and there is room enough for both. Mr. Hawtayne's scheme will in the end be carried out on purely commercial principles and intentions: Mr. Daniel's Society must always have, in order to carry out the views of its originator, a benevolent character, without being eleemosynary. If Mr. Hawtayne's plan should succeed, it does not appear to us that it would eventually supersede the necessity for Mr. Daniel's. It is certain, however, that Mr. Daniel's scheme must be considerably modified.

Our observations might be extended on this subject, important both to the non-Medical as well as to the Medical world. We cannot conceive for a moment that Society does not feel a deep interest in the happiness and welfare of the members of the Medical Profession; and knowing as we do, practically, personally, and professionally, how unsusceptible the body is of the poison of contagious disorders, (from which, as already stated, so numerous deaths occur annually amongst Medical men,) when the mind is cheerful, buoyant in hope, and secure (in the event of death) that the world's comforts still shall continue the widow's lot and the orphan's portion—in that very cheerfulness, hope, and security, the individual has the highest protection against the chance of catching infectious disorders, and the best safeguard, should he unhappily fall ill, against a fatal result. The same principle undoubtedly applies to every person; and equally cogent with them is the reason, to participate, as far as human foresight can, in the securities that Insurance Offices present to every member of the community.

The proportion of Medical men who die from the infectious class of disorders, is immeasurably great. Every fifteenth Medical man perished in Ireland during the last great epidemic. We have the fact further indisputably ascertained, that casualties are thrice as frequent among the Medical Officers of the Army, compared with the officers, who have, in addition to all the rigours of the campaign, the occasional opportunity of "glory" in the forlorn hope, "seeking the bubble reputation in the cannon's mouth." Of all classes of society, then, the Medical members therefore would seem to be trebly called on to support Institutions of the nature of those now submitted to them. It might be, perhaps, alleged, that the scope for such a society as Mr. Hawtayne's must be very limited *now*, considering the various institutions, divested of all class character, which are already established over the length and breadth of the land; and, therefore, it is unlikely to command the great object in such associations—numbers. So far, we allow this objection its full weight, but that is, we apprehend, altogether trivial; for it has been calculated, we believe, on tolerably correct data, that the number of assured to the whole population is little more than as 1 to 100. The range of insurance is by no means fully developed, and the very marked success which has attended almost every one established since the opening of the present century, so far as solvency is concerned, affords a tolerably fair presumption in favour of a new candidate for public confidence, particularly as that Association intends to embrace a class of insurers who have hitherto only been merged into the great commercial insurance bodies; their peculiar relations to society (decidedly a most serious omission, if not a positive blunder, in the framing and disposing of their claims and expectancies) being totally overlooked and discarded. There is one hint we would add, and it is this: that, as the times press stern and stiff around us all, no Medical man should decline to enter Associations such as these because he cannot secure what he might deem the happiest form of insurance; but let him insure for the smallest benefit, and afterwards augment his claims,—not reject a part because he cannot procure the whole.

It is understood that an early meeting is to be held for the purpose of giving the subject full consideration, and it will be our duty to see that every facility is given to the promotion of the extension of so praiseworthy and laudable a scheme.

ALLEGED ABUSES IN PRIVATE LUNATIC ASYLUMS.

Within the last few years great improvements have been made in the laws relating to lunatics confined in public hospitals or private asylums; but, even now, some fresh enactments appear to be necessary in order to correct abuses which are said occasionally to be perpetrated in the latter institutions. A benevolent legislature has endeavoured to guard the insane from those cruelties to which they were formerly

exposed, and they can now be consigned to our asylums without being whipped, goaded, or manacled. It was the boast of one of the speakers at the last Anniversary of the Bethlem Hospital, that the patients admitted there had that security guaranteed to them which was not enjoyed by those whose pecuniary means were such as to enable them to pay for attendance in private lunatic asylums. Here we have an intimation that it is possible for these establishments to be made the instruments of oppression and cruelty, and hence we are sure that gentlemen who are Superintendents of these houses will be anxious that means should be adopted to remove suspicions which still appear to attach to them. As Private Asylums exist for a class of patients who are enabled to pay for their board and medical attendance during the time they are detained, a notion prevails that some are kept in confinement when they ought to be set at liberty. The case of Nottidge v. Ripley has excited public attention on this point, and the Gloucestershire magistrates have, within the last fortnight, been engaged in examining into some charges against the principal of a lunatic asylum in the neighbourhood of Bristol. Into the truth or falsehood of these charges it is not our intention at present to enter; it is enough for our purpose that they have been brought forward, and in consequence the Chairman of the Board of Magistrates, the Rev. F. T. Witts, has proposed some important alterations as regards the government of private institutions for the insane. He states, in his Report, that abuses exist in these places which could not possibly occur in prisons. He says, also, that the investigations of himself and Dr. Lyon, at the Fishponds and Ridgeway, have resulted in the release of one patient from each house, leaving now there none but those *legally confined.* Such a statement as this, coming from a clergyman and a Chairman of a Bench of Magistrates, is calculated to produce a most unfavourable impression on the public mind in reference to private asylums, tending, as it does, to show that they may be made prison-houses for persons against whom a mere charge of insanity is brought while they are yet in the enjoyment of a sound mind.

The Chairman, in the course of his Report, commented on the Law of Lunacy, stating that it is divisible into two parts—the one relating to public and the other to private asylums. The law for the poor is founded on publicity, that for the rich on secresy and seclusion. The tendency is to produce opposite results—of kindness and relief for the poor, and of severity and retention for the rich. The Chairman, moreover, reiterates that which has been before stated —" that it is the interest of the proprietors of private asylums to obtain and retain patients, and, while maintaining their bodily health, to hurry them through the several gradations of mental disease, till imbecility finally supervenes." He contrasts, moreover, the advantages which result to those who are placed in public asylums —the buildings being erected in accordance with the most scientific principles—the officers selected from many highly qualified candidates; while private institutions "are generally not built, but adapted for the purpose for which they are intended." That there is much truth in this statement few can doubt, while at the same time it must also be admitted that there are many private asylums built upon the most approved plans, and conducted in the best manner.

In order to remedy existing evils, it is proposed that in the cases of persons not paupers, but who are unable to bear all the expenses necessarily connected with their confinement in private asylums, the magistrates in petty sessions, and after hearing evidence upon oath, should have the power of determining what proportion of the required sum should be paid by the parish, and what by those relatives legally liable to aid in relief. To remedy improper arresting of persons and confining them, also the giving of improper certificates, the Chairman would have for all classes, above paupers, the order for arrest issued only by a magistrate, upon a written declaration, on oath, of the insanity of the patient, with a sworn written statement of the circumstances forming the reasons for such declaration:—

"Upon his summons, let two certifiers, each a practising physician, being a licentiate of the College of Physicians, or a practising surgeon, being a member of the Royal College of Surgeons, each previously sworn, and neither connected with the proprietor of the asylum for which the patient is destined, separately examine the patient. Let each certificate be founded upon a sworn written declaration of his insanity, with a sworn written statement of the facts forming the reasons for such declaration, and be signed by the certifier only after the examination of the patient and of others, the latter upon oath, taken in writing, and in the presence of a magistrate, countersigning the same, and appending one copy of the examinations to the certificate to which it belongs, and giving another copy to the patient.

"Let him then annex his warrant for the patient's reception at the intended asylum."

Certain regulations are also proposed "for the accommodation in private asylums of the insane imprisoned frequently for double the number of years, that the worst felon is months." The Report suggests further, that in no instance should a certificate be received from "a mere country apothecary; but, from a member of the Royal College of Surgeons or Physicians." And who is the "mere country apothecary?" We think that nine-tenths of rural Practitioners possess the double qualification; and we are quite sure, that Shakspeare's man,—

"With tattered weeds and overwhelming brows,
Culling of simples,"

has long since passed away. We are compelled to admit, however, that the "mere apothecary" and the member of the Royal College of Surgeons have both been defectively educated in Psychological science. It is a department of medical education which our Corporations have most improperly neglected. Neither the College of Surgeons nor the Apothecaries' Company requires students to have attended Lectures on mental diseases, and institutes no examinations on these subjects. We doubt, in fact, whether either of the Courts are capable of entering upon the matter at all; for the present, therefore, the science of Psychology will be neglected by a large number of medical students. The magistrates' sarcasm should not be without its influence upon the College and the Hall. We have stated, in another column, that they are now appearing to act in unison as regards their system of education. It yet needs to have engrafted upon it a course of instruction on mental diseases, and the members or licentiates of that Corporation which first demands it, will be best qualified to give a certificate.

To improve medical education is a duty imperative also upon our licensing Corporations, in order effectually to prevent persons of sound mind from being incarcerated in private asylums. It is desirable that real lunatics should be early brought under a course of proper medical treatment; but, it is also right that the liberty of the people should be in no way endangered. There are cases in which the nicest discrimination is required; but if the medical attendant has neglected to cultivate Psychological science, how is he to decide according to the principles of rectitude and justice, when cases of alleged insanity are brought under his notice. We, therefore, feel called upon to entreat our Corporations to fulfil a duty which they owe to the Profession and society, by commanding all medical students to attend a course of instruction on mental diseases; and to examine them on these subjects. Then, with a few more salutary Enactments for the better regulation of Lunatic Asylums, and we shall rarely hear of there being confined within their walls sane persons.

THE ENGLISH APOTHECARIES' COMPANY AS A LICENSING MEDICAL CORPORATION.

A fortnight ago we informed our readers that the English Apothecaries' Company had issued a new curriculum, which cannot fail to exercise an important influence upon the rising generation of Medical Practitioners. We consider this circumstance, therefore, as an important era in our Profession, and it naturally directs our attention to the singular position which the Corporation occupies in it. In no other country does such an anomaly exist as an Apothecaries' Company giving laws to medical men; and the whole history of this Institution serves to exemplify our peculiarities as a nation. In most of the Continental Kingdoms the Apothecary is the mere dealer in drugs and chemicals; in England, he is the Physician in ordinary of the people, who dispenses his own prescriptions. He is, therefore, the true ιατρος of the Greeks, and *medicus* of the Romans; for the Physicians of both these Republics prepared the medicines ordered by themselves. The term apothecary, applied to a section of the English Medical Profession, is a misnomer; yet the Corporation, through whom this name has been entailed and perpetuated, by a singular necessity, has been compelled to amalgamate that which ought to be for ever separate, viz., science and trade.

In an obscure lane, in this great Metropolis, stands a building, having no pretensions to architectural beauty, and without any indications that it is a city hall, except a painted board with gilt letters over one of its doors, and armorial bearings, with unicorns as supports, and a hog in armour,—this is the house of the English Apothecaries' Society, and one of the seats of Government of the Medical Profession. An examination of this structure shows that it is divisible into two parts,—the

one devoted to trade, the other to science. The shop is the most imposing part of the building, —the entrance for students and candidates for the diploma being by an arched door-way, within which is the beadle's office. Those who have sought the "license" say, that the only things of note, after you have passed this portal, is a large clock and a gloomy "funking-room." But this uncouth building is a relique of antiquity with which is associated much that is interesting to the members of the Medical Profession.

That modern Solomon, who could with equal facility break a lance with a bishop, or write "a counter-blast against tobacco," gave to the Apothecaries' their original Charter. Previously, they had been associated with grocers, and this incongruous union had been the means of preventing pharmacy, in England, from making that progress which it had made in other European kingdoms. Here, however, the Apothecaries early begun to practice medicine as well as sell drugs and compound Physicians' prescriptions. At the commencement of the last century, the College of Physicians disputed the right of the sellers of drugs to exercise the healing art, which, however, was established by the celebrated decision of the House of Lords, in the case of the College against Rose; and the Apothecaries from this time have acted without molestation as Medical Practitioners. The law passed in 1815 invested the Company with most important privileges, and it is to this we must ascribe the progress which has been made in medical education by what are now called General Practitioners.

The College of Surgeons, at the commencement of the present century, had received a charter of incorporation, but had done little to promote the real welfare of the Profession. The Apothecaries Act, however, served, in some measure, to rouse the College from it lethargy, and, from time to time, it extende its educational course in order to keep pac with the Company, and we find them now issuing regulations in common with eac other. The Society has, therefore, done wel for the Profession in the matter of medical education; its existing curriculum being equa to that of any University or College in the kingdom. But the question arises,—Is such an Institution a proper one to rule in the Medical Profession? We think that it is not, and with this opinion the present rulers of the Company agree. We arrive at this conclusion from the fact, that they have offered, on certain conditions, to surrender the privileges conferred upon them by Act of Parliament. The constitution of the Society, as a Medical Institution, is most defective. The Court of Examiners must be chosen from members of the Corporation; and while this Court is now composed of intelligent professional men, it may hereafter not have a single individual in it who knows anything of Medicine. We are bound to look beyond the present to the future, and it is possible for the Apothecaries' Society to be the means of doing as much injury to the Profession as it has done good. It must always remain a trading Company, for the *members* have invested a certain amount of capital, and expect profitable returns: if, therefore, druggists, or any bold speculators, should obtain a majority and seize the reins of government in Water-lane, the sale of certificates would be looked upon as a most important item in business, and every means adopted to make it as extensive as possible. The old licentiates, having no corporate privileges, would be unable to check their Mammon-loving rulers, and the consequence would be, that persons with scarcely any knowledge of Medicine would be sent forth with authority to practise it.

While, then, we give credit to the Apothecaries Company for what it has done, we have no wish that it continue a licensing institution. We would not, however, have its privileges taken away, except for the purpose of conferring greater benefits on the Profession.

VITAL STATISTICS, AND PUBLIC HEALTH IN SCOTLAND.

We have just received intelligence of the Bill for the registration of the Deaths in Scotland being withdrawn—the registration of Births was a part of the same Bill; along with this perishes the separate Registration of Marriage Bill; and also that for extending the Public Health Bill to Scotland. All these Bills are necessary to place Scotland on the same footing with other civilized nations,—why, then, are they resisted, and successfully resisted, by Scotsmen too, in the Imperial Parliament? Free Institutions are above all price; otherwise we might be tempted sometimes to count the cost, when a handful of senseless or interested agitators by abusing the liberty they are unworthy of, can defeat measures of general utility. And, in truth, petty agitations are becoming a nuisance. The addle-headed too often get the upper hand. The sensible part of the country stands too much aloof, declining to be roused to action, but on occasions which it deems worthy of its interference. It is of small avail to place able men at the helm of affairs, if all that is little in the country is left at liberty to hang on their skirts and impede their onward progress.

Our chief regret is for the indefinite postponement of the exact Registration of Deaths. The science of Vital Statistics is well known to be of particularly slow growth, and in Scotland there is still the very foundation to lay. Thus we have the more cause to lament, because Scotland, owing to its smaller extent, and by reason of some peculiarities in its Institutions, offers a more favourable field for bringing out precise results than most other countries; and how desirable this is, no one can look into almost any question, in which Vital Statistics are concerned, without feeling in the strongest manner. With an intelligent Registrar, able to appreciate the importance and the difficulties of his task, and having the power to regulate the nomenclature of diseases to be employed in the Registration, and to enforce uniformity, we might hope, in no very long time, to see a body of details collected, which, when properly methodized, would place the science at once a step higher in the ranks of exact knowledge.

As to the Public Health Bill, we fully expected that it would pass, and so modified that it would have saved Scotland from the direct interference of the London Central Board—the body which has there reaped such golden opinions for its proficiency in Medical Logic. We have the more reason to regret the withdrawal of this Bill, that the Nuisance Removal and Contagious Disease Prevention Act applies to Scotland as well as to England; and thus, as far as its provisions are concerned, Scotland is left, without restriction, under the control of the Central Board. One thing is certain; till they show themselves better entitled to confidence in their wisdom and discretion, they need expect no co-operation from the Medical Profession.

THE OPERATIVE SURGERY OF JOHANN FRIEDRICH DIEFFENBACH.

EDITED BY J. STEVENSON BUSHNAN, M.D., Fellow of the Royal College of Physicians of Edinburgh, &c., &c., &c.

In my last I offered a few preparatory remarks upon Dieffenbach's great work, and the plan I proposed to pursue in presenting his views and opinions to the English reader; and now, passing over the history of Surgery, we arrive at

THE FIRST PART.

CHAPTER I.

THE EXTRACTION OF FOREIGN BODIES.

(*Extractio Corporum Alienorum.*)

The subject of foreign bodies in the organism is most comprehensive. To it, in the widest sense, belong not only foreign heterogeneous substances forced into the body from without, but likewise calculus formations, incrusted excrementitial matters, and portions of dead bone; each as alien to the organism as a fragment of wood, a bullet, or a splinter of glass.

I. To the first series pertain those which surround a projecting part of the body, and determine accidents, as, for example, finger-rings.

II. To the second those which are impacted in the natural inlets and outlets of the body; foreign bodies in the nasal cavities, in the gullet, in the rectum, &c.

III. To the third series belong those hard substances, the entrance of which is attended with injury, as for instance balls and splinters.

IV. To the fourth appertain those formerly connected with the body, but, having become dead, are extraneous; bony splinters, portions of necrosed bone, and the like. Calculous concretions will be treated of under the head of operations for the stone.

1. *Removal of firmly attached and constricting foreign bodies from projecting parts of the body.*

The removal of foreign bodies which constrict projecting parts is sometimes attended with great difficulty, more especially when they have caused inflammation, and burrowed so deeply into the textures as to be scarcely discernible. These are generally finger-rings, or strings or cords fastened round the penis during relaxation, to prevent seminal emission, and which give rise to continued erection and inflammation.

Gold and silver rings are most readily nipped across in a slanting direction by means of sharp wire-shears, nail or bone nippers, the point of one blade being insinuated as far only as one half of the ring, and the section finished at successive intervals. It is generally impracticable to use a file in consequence of the swollen condition of the skin. I have always divided rings. The narrowness of the space will rarely admit of the interposition of a leathern strap for the protection of the integuments. When the ring is divided the cut ends may be twisted asunder with a couple of pliers.

A similar mode of procedure may be adopted with regard to rings fastened on the penis; their removal is attended with more difficulty, however, and not unfrequently rupture of the urethra ensues.

Owing to excessive swelling of the member, and approaching gangrene, the integuments are so much elevated above the foreign body as to conceal it entirely from view. In this case, an incision several lines in length ought to be made without delay forwards or backwards on the dorsum, or along the side of the penis, in the healthy integument. A director, slightly bent inwards, is to be introduced into the opening, passed beneath the skin or the cord or ring, and the whole divided with a curved bistoury, as in the operation for paraphymosis. If a metal ring be present, it should be divided with wire shears. The after-treatment is to be adapted to the amount of inflammation.

A young man put the ring of a key round the root of the penis, whereupon such extensive swelling supervened as to require scarification. Not till then could it be withdrawn. In a similar instance, an iron ring was removed by the aid of a file. Another youth contrived to force his penis and scrotum through the oval slit of a steel for striking fire. As the parts soon became excessively turgid, it could not be got away. It was impossible, moreover, on account of the hardness and thickness of the metal, to use a file or saw. By happily adapting a couple of screw hand-vices, the steel was riven across, any detriment to the patient.

II. THE REMOVAL OF FOREIGN BODIES FROM NATURAL CAVITIES, WITHIN REACH OF THE SURGEON.

1. *The removal of foreign bodies from the nasal cavity.*

Foreign bodies in this locality are met with most frequently in children of from three to six years old. Their abstraction is often very difficult, especially when they have caused swelling, are firmly fixed, and situate high up. The most common are leguminous seeds, peas, beans, little stones, glass beads, bits of wood, pipes stalks; in the instance of adults, ends of pipes, buttons of foils, fragments of pincers, silver-wire left behind after attempts to remove polypus, dossils of lint, blotting paper, and compressed spunge, which may have served as plugs, to check hæmorrhage.

In the first place, it is requisite to ascertain the nature of the foreign body, and also the nostril in which it is lodged. For this purpose, the patient being seated facing a window, the surgeon gently introduces a blunt silver probe, curved at the end, and moistened. The substance, if small, and not wedged in, may be directly extracted with the probe, insinuating the concave side of the instrument behind it, and securing it in a favourable position. Sometimes the irritation excites sneezing, and whenever this can be foreseen from the grimaces of the patient, sudden pressure is to be made on the opposite nostril, whereby the body will be expelled through the current of air and the concussion. This will occasionally follow a pinch of snuff.

Should the first attempt fail, and the surgeon be aware of the situation of the foreign body, the head is to be thrown back, supported by an assistant, while with the left hand he presses upwards the tip of the nose. If the subject be a child, he takes a strong silver director, bent at the end like a flat hook, passes it from below upwards round the extraneous substance, lowers his hand in order to elevate the point, and withdraws it in that direction. For infants an oculist's curette will be found suitable. When the substance is firmly fixed, and cannot be got away with the above instrument, a small pincer may be employed, in the manner of a polypus forceps, one blade being directed upwards, the other downwards. The expanded blades being made to grasp the body, a few gentle to and fro movements are performed, and the extraction achieved. It is not safe to exercise much pressure in the instance of glass beads, lest they break, or even with regard to swollen beans or peas, lest they be crushed. Residuary fragments often create more mischief than the original mass. These are best removed with an ordinary forceps.

The dislodgment of firmly impacted hard substances from the nostril is frequently difficult. I generally use a straight polypus forceps. The manipulations here are the same as for the torsion or extraction of solid nasal polypus. The hæmorrhage is ofttimes considerable; to be arrested only by cold injections and cold applications to the forehead and nose. Where the foreign body is too large to pass the nasal orifice or to be pushed into the throat, it is necessary to divide the ala nasi. Bulky substances alone ought to be propelled into the gullet, because, if small, there is the risk of danger of their dropping into the windpipe. Bits of sponge, lint, and other kinds of plugs are readily withdrawn by the aid of polypus forceps, after water has been previously squirted up. To allay pain and inflammation, tepid injections of decoction of mallows may be thrown into the nostrils.

2. *The Extraction of Foreign Bodies from the Antrum Highmorianum.*

This is seldom called for, as these rarely effect an entrance through the narrow concealed aperture. On the other hand, it now and then happens that bullets or grains of corn lodge here, either driven in from without, or which have worked their way through an alveolar opening caused by caries. Their removal is accomplished by the same method as that for polypi in this situation; namely, by introducing a small forceps through a perforation in the alveolary process. (See "Opening of antrum.")

3. *The Extraction of Foreign Bodies from the External Auditory Passage.*

This is often indispensable in the instance of children who have stuck peas, beads, berries, portions of chalk or stone in the ears. These are most readily scooped out with a curved director or a curette; if in the anterior part of the auditory tube with forceps. In adults the meatus is sometimes blocked up with dead insects, plugs of cotton, and other things incrusted with cerumen, or with indurated cerumen itself. These, the cause of continued deafness for years, are best extracted with moderate sized polypus forceps. It is advisable to drop in beforehand a little almond oil, and allow the patient to recline upon the opposite side of the head. Great caution is to be observed, so as not to injure the walls of the meatus, or the tympanum. Should violent bleeding supervene, and there be no likelihood of completing the operation at one sitting, cold, and afterwards warm, applications are to be resorted to, so as to favour suppuration. Subsequently, when the parts are relaxed, the substance may be extracted. Fabricius Hildanus witnessed hemicrania, debility of the entire half of the body, obstinate cough, amenorrhœa, epilepsy, and wasting of the arm ensue from the circumstance of a bead having been forced into the ear. Restoration to health followed its abstraction. Sabatier saw typhus fever and death consequent upon the pressure of a pellet of paper in this situation. Power observed protracted salivation and atrophy result from a dossil of wool. I have noticed, after the removal of foreign bodies, long impacted in the ear, that the hearing became so acutely sensitive, as to require the ears to be stopped with cotton. Should a living insect create any distressing symptoms, it may be picked out by the aid of a tuft of cotton fastened to the end of a match; or killed with a drop of oil, and then readily extricated. Solution of acetate of lead, dilute cherry-laurel water, and a weak solution of corrosive sublimate have been used for the same purpose. Comperat destroyed an insect larva in the meatus auditorius by means of tincture of opium. Andry states that a round worm crept along the eustachian tube into the ear.

4. *The Extraction of Foreign Bodies from betwixt the Eyelids and the Eyeball.*

These are of every variety, mostly grains of sand, particles of lime, insects, seeds, and the like. They either lie free between the lids and ball of the eye, or are imbedded in the surface of the cornea or sclerotica,—for example, splinters of steel. Foreign bodies, situate beneath the eyelids, are easily removed, provided these are not inflamed and can be held apart. If situate under the lower lid, this is to be depressed with the left index finger, held firmly upon the skin. If under the upper lid, the central eyelashes are be seized with the fingers, and the lid gently dragged from the globe; then, upon the patient throwing his head backwards, the operator keeping his eye fixed on the intervening space, withdraws the mote by the help of a blunt forceps. The curette answers well when the substance is round; dust, sand, and the like are got rid of by a hair pencil, together with aqueous injections; acrid matters as gunpowder, salt, pepper, by means of a pencil soaked in almond oil. Irritant chemical substances are neutralised by appropriate liquids, and their effects counteracted by a strict antiphlogistic after-treatment; if the eyelids are greatly swollen, they must be carefully opened, and then syringed with warm milk.

Foreign bodies, which penetrate and are firmly fixed within the inner membranes of the lids, are not easily reached, especially when the eyeball is much inflamed and the eyelids are closed from inflammatory swelling. When such is the case previous resort must be had to local or general bloodletting, cold applications, and where the substance has remained a considerable time to tepid, mucilaginous, and narcotic applications. The speculum is seldom admissible from the risk of irritating the eyelids.

If the penetrant body is sharp, angular, and firmly imbedded, it must be removed at all hazards, for fear of its perforating the eye-ball. Where it cannot be picked out with forceps, and is endangering sight, the external commissure of the lids ought to be snipped. The section of the conjunctiva is generally required for its elimination.

For the removal of minute bodies projected into the membranes of the globe, as tiny splinters of metal, glass, flint, or points of needles, the forceps of Professor von Ammon is convenient, the eyelids being held asunder with the ordinary speculum. Very small splinters are most readily extracted with a cataract needle. The surgeon may occasionally avail himself of the hooks employed in strabismus operations, for the purpose of fixing the eye. In the instance of seeds of corn, which do not perforate the eye, it is generally necessary to dilate the minute aperture with a fine cutting instrument, ere they can be withdrawn with the forceps.

When the foreign body has remained so long as to have got incased in a capsule, a slight incisision is to be made, after which it may be picked out with the point of the knife or with forceps.

5. *The extraction of foreign bodies from the larynx or air tubes.*

The extraction of foreign bodies from the air-tubes is an impracticable operation, partly owing to the physiological structure of the parts, and partly to the coincident irritation. The slightest attempt of the kind augments the jeopardy to life. If it be a pointed body, as a needle or a fish-bone, there is always a chance of its having stuck in the superior portion of the wind-pipe. Here, after depressing the tongue with a spatula, it may be seized with a long forceps. Small round substances are apt to fall into the windpipe, and occasion by their ascent and descent, during the act of respiration, the most alarming symptoms. How are they to be secured? With forceps? Death would inevitably follow the experiment. Desault alone proposed the passing of an elastic catheter from the nostril into the trachea.

As a general rule, the foreign body, if of small dimensions, as a pea or little bean, after having lodged for a while in the trachea, drops into a bronchus, commonly the right, because that is shorter and wider than the other. After careful dissections, I have always found it in the right, and never in the left bronchus. It will seldom be evacuated by sneezing provoked artificially, by coughing, vomiting, or by inclination of the head forwards. Only by prompt opening of the larynx or the trachea, can life be saved. All other means are fruitless. Its exact position can be rarely ascertained by percussion, inasmuch as it is constantly shifting to and fro during the first period after the accident, through the movements of respiration and cough.

REVIEWS.

On Gout; its History, its Causes, and its Cure. By WILLIAM GAIRDNER, M.D. 8vo. Pp. 240 London. 1849.

When we first took up this unassuming, little volume, we felt strongly inclined to ask if there were any necessity for a new book on gout. Whatever our opinion on the point may have been, we can now assure our readers, that we have derived much pleasure and instruction from Dr. Gairdner's treatise. Our Author is one of those men—we wish there were more of them—who, after having spent many years in the active pursuit of his profession in this great metropolis, feels that he owes it to his brother-practitioners to record the results of his personal experience, and to give utterance to the opinions which he has formed on the important subject to which his volume is devoted. We shall not follow him in detail through the various chapters of his treatise. Passing over the first chapter, which is general and introductory, we find, in the second chapter, a good description of the different species of gout, and of the different stages of the disease. In treating of the sequelæ, the changes occurring in the joints and muscles, or the functions of the stomach, bowels, and organs of circulation, and in the tone and energy of the nervous system, are duly noticed. The terminations of the disease are then noticed.

"One of these is apoplexy. The same disposition to the deposit of earthy matter, which is so manifest in the articulations of the limbs, is equally evident in the arteries and veins. Their friable coats can no longer bear even the diminished impetus of the blood. But, though the heart is now acting with less energy, the pressure of the circulating blood is, for various reasons, oftentimes greater than before. The limbs and moving powers, it is true, have diminished in bulk, but the belly is more protuberant. Fat has accumulated around the great viscera, which, joined to the congested state of these organs themselves, and the impeded circulation through them, forces an unnatural flow towards the head and brain. The records of Medicine are full of examples of apoplexy, consequent on, and arising from, gout.....

"Another termination of gout is menorrhagia to women at the age when they usually cease to menstruate. This is very frequently seen in a mitigated degree. As it is generally at this period of their lives that women are attacked by gout, the discharge of blood often serves the purpose of a vicarious disease and a cure. It generally alarms them much. There are cases, however, in which they are very justly alarmed. The loss of blood goes the length of extreme and dangerous flooding. But such cases are rare, and generally occur in women of loose fibre, of indolent life, and of self-indulgent habits in matters of diet.

"The same observations will apply to the case of bloody discharges from the bowels,—a far more frequent termination of gout. Hæmorrhoidal bleedings are very profuse, but they give less alarm, though they are liable to be confounded with hæmorrhage from the vessels of the portal system, which latter are characterised by their dark fluids, of the colour and consistence of pitch. These terminations — apoplexy, menorrhagia, hæmorrhoids, and melæna—are but varieties of the same affection. The seat is different, the disorder is the same. Hæmaturia is often mentioned as a consequence of gout. It is rare, even as a symptom. I never saw it terminate the disease. Hæmorrhoids, indeed, and menorrhagia, though they frequently put an end to gout, seldom do so after the manner of apoplexy and melæna, by putting an end to life, but by bringing on the next, the most common and the most alarming occurrence in gout, viz., dropsy, which now claims our notice.

"The most usual forms of dropsy in gouty subjects are hydrothorax and ascites, caused by the imperfect functions of the great excretory organs, the liver and the kidneys in this, and by the disturbance of the heart in that, form of the disease. General dropsy, or anasarca, is much more rarely seen in gout. It cannot surely surprise any one, that a disease which has its principal seat for many years in the central organ of the circulation, should terminate at last in dropsy. The commencement of the dropsical affection is obscure, and the attack often evanescent. It is very common to observe a manifest fluctuation, which has disappeared the next day. A similar remark may be made regarding the water on the chest. It is not unusual to see a gouty patient oppressed with what he calls his asthma, and to receive plain indications, through the stethoscope, of the presence of liquor on the chest, and yet to find these symptoms disappear in a few hours. This is easily explained by relief given to the action of the heart." Pp. 30—33.

These are the terminations of gout which are attended with alteration of structure and destruction of organs; but, as our Author truly observes, gout is sometimes the cause of death, without any intervening processes, like those we have mentioned. He believes that the cases of sudden death, so often heard of in gouty persons, are, in many cases, "only syncope, too profound, and too long continued," and gives cases illustrating this opinion.

There are many passages in Dr. Gairdner's volume which we would gladly transfer to our columns, did our space permit. We must, however, proceed to that portion of the work which has the greatest *practical* value, we mean, the chapter on the treatment of gout. The first remedy he mentions is *blood-letting*. We believe we are expressing the opinion of nearly all those members of our Profession whose position entitles their opinion to any weight, in asserting, that ordinary venesection is hurtful rather than beneficial in gout. Dr. Gairdner agrees with us, that bleedings to such an amount as is necessary to subdue inflammation, are much to be avoided in gout; he is, however, a warm advocate for such bleedings in this disease. He states, that the removal of from three to six ounces of blood, instead of weakening the system, acts as a tonic, and supplants the use of purgatives, which are often noxious in gout, and are sometimes attended with considerable risk. The arguments he adduces in favour of this mode of treatment, are so convincing, that although, as a general rule, we hold blood-letting in abhorrence, we shall certainly give his "small bleedings" a fair trial.

The following remarks on purgative medicines evince sound practical knowledge:—"For some years past I have made little use of the neutral salts as aperients in gout. The profuse watery evacuations to which they give rise are, I think, injurious. The warm, and even the more powerful vegetable aperients, such as senna, rhubarb, aloes, jalap, and scammony, seem to me far better adapted to the constitution of the gouty. They may be given with great advantage in the form of tincture, also associated with the warm aromatics and tonic bitters." Every practitioner of any experience becomes unconsciously attached to certain remedies.

We have promised to give Dr. Gairdner's "small bleedings" a fair trial; let us ask him in return to try our favourite aperient in these cases, namely, sulphur and sulphate of potash, with or without a little rhubarb. Ten grains of *pure* sulphur, (not the admixture of sulphur and sulphate of lime, most commonly called sulphur,) an equal quantity of sulphate of potash, with, occasionally, the addition of five grains of rhubarb, form a combination which we are sure will not disappoint him in these cases.

The alkalis and their carbonates find no favour in our Author's eyes. He regards them as "wholly inefficacious," and states, that he has never seen the uric acid of the urine disappear, or even in any marked degree diminish under their use, whilst this change is speedily accomplished by the administration of the alkaline phosphates, tartrates, and citrates.

The observations on the true value of colchicum in gout, and on the mode of administering it, constitute perhaps the most valuable section of the whole volume. It is well known that Christison and other high authorities maintain that this drug never produces its full effect, till it has produced griping and purging. Our own observation has long shown us the fallacy of this opinion; and we fully concur in our Author's view, that "colchicum never more effectually relieves the patient than when it acts silently and peacefully, without producing any evacuations whatever, or in any way disturbing the patient's comfort and ease."

Although our limited space will not permit us to enter into the consideration of the final chapter on the treatment of metastatic gout, we can assure our readers that they will find much profitable matter therein. And in summing up our remarks on the volume generally, we may observe that no one can rise from its perusal without the conviction that it contains a trustworthy history of the disease, that it conveys sound directions for treatment, and that it is the work of a physician who, amid the wearying toil of a large and successful practice, keeps himself thoroughly conversant with all the recent advances in physiological science, both at home and abroad.

The Journal of Psychological Medicine and Mental Pathology. Edited by FORBES WINSLOW, M.D. No. VII. July 1, 1849.

The present Number of this excellent and interesting Journal fully maintains its just claims to the consideration and support of the Medical and Philosophical reader. The articles are various, and some of them are of high literary and scientific merit. The two which are the least to our mind are, the one "On the Insanity of Dean Swift," and the other, "On Sleep and Sleeplessness." The first certainly furnishes no additional information on the subject of which it treats, nor is there the slightest novelty in the anecdotes related. The writer makes the article a medium for an attack upon phrenology.

"We may here remark," he says, "and the fact is anti-phrenologically important, that the immediate effect of pressure within the skull is to attenuate the *internal* table without producing any corresponding elevation of the *external* table."—(P. 369.)

Where the writer picked up this valuable information, he does not state. The assertion might have passed current thirty years ago, but it is ridiculous now. If the external table is not modified in any degree by the changes in the capacity of the brain, how does it happen that the size and form of the adult head are so widely different from those of the infant? If all the pressure be upon the *internal* table, is it not evident that the skull would always have the same capacity? What is to make it otherwise, if the pressure is strictly limited to this table? The whole argument is about as philosophical as it would be to contend, that when a man puts his legs into two pairs of stockings, the inner pair only adapts itself to the form and pressure of his limbs. For the refutation of such observations, it is not necessary to appeal to phrenological authorities, but simply to common sense. He further observes—

"But after all, the success or non-success of a phrenological interpretation, will depend very much on the skill and ingenuity of the expositor, which as clearly evinced in the case of Raphael, upon a cast of whose skull Spurzheim and Combe lectured for many years, showing how the organology precisely corresponded with his artistical genius, his conduct to the fair Fornarina, and even the disposition of his property in his last will and testament; after which it was discovered that they had been lecturing upon a wrong skull."

We had thought that the time was gone by for these wonderful stories. The writer must be living upon an old stock of mental goods, which he had not the fortune to dispose of when they were marketable.

The Article on "Sleep and Sleeplessness" will interest the general reader. It exhibits considerable taste, and is elegant as a composition. The writer, however, is not equal to the grasping of the subject, which is one of the most important and difficult in the wide range of physiological investigations.

We would particularly direct the attention of the reader to the Article on "Juvenile Delinquency and Degeneration in the Upper Classes of Society." It is philosophical and just in its views throughout,

and the writer is unquestionably a man of very superior mind. This Article alone is far more than worth the cost of the Journal. If the talented and enterprising Editor continues to secure the services of men of this mental calibre, he may lay aside the anxieties necessarily connected with his undertaking, satisfied that the public will not have to be coaxed or entreated to purchase. His labours will be certain to command a ready market.

There is, also, an elaborate Article on the "Lunatic Asylums and Insanity in America," which is particularly worthy of attention. On a subsequent occasion we may probably give an analysis of it. Dr. Ogier Ward furnishes a very interesting "Case of Double Consciousness connected with Hysteria." Our brief space, however, will not permit us to enter upon its consideration, or on that of many other articles equally worthy of notice. We must refer the reader to the Journal itself, and the perusal of it will well repay him.

Dr. Forbes Winslow has, nevertheless, a further claim upon our limited space. He contributes an admirable Article on the "Ramollissement of the Brain," resulting from impairment of mind. It is the best article on the subject we have read. It is just; comprehensive, and practical in its views, and we trust he will concentrate his energies and talent in this direction. He may rest assured that the field on which he has entered is richly worthy of cultivation, and few men possess superior opportunities to himself for doing justice to it. The facts he brings forward are based on extensive observation; and he shows a tact and discrimination in tracing the early manifestations of the disease, which are highly creditable to him. They are always rare qualities in the physician, and far more valuable than an understanding teeming with the knowledge of others. They can be acquired only in the intimate associations with mankind, and then exclusively by those whose powers of mind are peculiarly fitted to observe and analyse.

Dr. Winslow points out the causes giving rise to this softening of the brain, and from the cases he adduces, and the remarks which accompany them, clearly proves how necessary it is that the initial symptoms should be detected, as it is then only that there is a possibility of arresting the progress of the malady. The existing state of society is fruitful in the production of such cerebral disorganisation. The full stretch of the mental faculties in every walk of life, characterised by vigorous and uninterrupted efforts to obtain wealth, distinction, honours, or the means of existence, is constantly making demands upon the brain to which it is unequal, and hence the inevitable result—it breaks down, and presents, in its wreck and wretchedness, every form of mental disease. We say, in the words of Horace,—

"Dum vivimus vivamus."

CONVENTION OF POOR-LAW MEDICAL OFFICERS.

[To the Editor of the Medical Times.]

SIR,—The Committee having sought for an interview with the General Board of Health, relative to the additional onerous duties imposed on the Poor-law Medical Officers by the recent orders of that Board, in consequence of the prevalence of cholera, and received the following reply to their communication, I shall feel obliged by your publishing it, together with the few remarks I have to offer on the subject.

(Copy.)

The General Board of Health,
Gwydyr House, Whitehall,
July 14th, 1849.

Sir,—I am directed by the General Board of Health to acknowledge the receipt of your letter of the 13th instant, in which you call the attention of the Board to the additional onerous duties now pressed upon the Poor-law Medical Officers by the recent orders in reference to cholera, and request the Board to name a day for receiving a Deputation from the Medical Officers Committee on the subject; and I am to state in reply, that the Board are unable to enter into any of the questions connected with the Union expenses incurred in carrying out the provisions of the Nuisances Act, and hence it would be improper for them to entertain the subject of the extra remuneration to which the Medical Officers may be entitled under present circumstances. They have, therefore, to express their regret that it is not in their power to comply with the wishes of the Committee. The question is one that must be decided by the Guardians and the Poor-law Board.

I am, Sir, your obedient servant,
ALEX. BAIN, Assistant-Secretary.

Chas. F. J. Lord, Esq., Hon. Sec.,
Committee of Poor-law Medical
Officers, 4, Hanover-square.

The reply throughout shows the manner in which officials coolly place burthens, hard to be borne, on other people's backs; while the last sentence of it imposes upon the President of the Poor-law Board an additional obligation to exert the power, which he undoubtedly possesses, to secure common justice to the Medical officers acting under the Poor-law Commission.

The trouble and interest taken by Mr. Garlick, of Halifax, to exhibit the false position in which Union Surgeons are placed, is well known to the medical public. Last week I received from him a somewhat private letter, which was, however, subsequently read to the Committee, since which, that gentleman's consent to its publication has been obtained. It forms so good "a rider" to the Letter from the General Board of Health, and is so "*apropos*," that it would be well to insert it here, that Mr. Garlick's zeal and public spirit may induce other officers to make similar exertions.

(Copy.)

Dear Sir,—Enclosed I beg to hand you a few copies of the "Summary" drawn up by me. It has already been laid before the Poor-Board, and a copy has been forwarded to the *Times, Morning Chronicle, Sun, Daily News, Punch, Halifax Guardian, Leeds Mercury, Intelligencer* and *Times, Manchester Guardian, Wakefield Journal*, and *Bradford Observer*.

I hesitate not to give Poor-law Medical Relief every publicity in my power, and, for this purpose, I note down accurately the various items, so as to enable me to do so with precision.

I am ready to take an oath as to the correctness of the tables I send you, as the work has been entirely performed by myself, and no person but myself has made an entry in my book. I have met with the greatest insult from the Board of Guardians of this Union; but that will not cause my spirits to flag, nor, if my health be spared, will it prevent a periodical full exposure of the way in which the Medical relief of the poor is made to fall where it was never intended, at least I hope so, viz., on the shoulders of the hard-worked Medical Officer. Wishing you all vigour and success,

Believe me to remain, dear Sir, yours truly,
FREDERICK S. GARLICK.

5, Cheapside, Halifax, 6th July, 1849.

Excuse great haste; I will address you again in a few days.

To C. F. J. Lord, Esq., Hon. Sec. to the
Poor-law Medical Convention.

I may be permitted to state also, that during the past week, a very valuable Petition in favour of an improved system of Poor-law Medical Relief has been obtained through the exertion of Mr. George Cowley, of Winslow, and signed, in addition to the medical men, by all the clergy and magistrates of the district,—by the Chairman—two Vice-Chairmen, and several other Guardians of the Union Board, which was submitted to the Committee at their last meeting, previous to its being placed in the hands of Mr. Disraeli, the county member, for presentation, who it is hoped, in future, will further the objects of the Convention.

The Poor-law Medical Staff will ultimately owe its emancipation in a great degree to strenuous exertions similar to Mr. Cowley's and Mr. Garlick's—to exertions made by an honest, hearty troop; daily growing stronger, "Who never knew—when man to man is true—a fear,"—to exertions made, and in the spirit of the following well known lines:—

"Hereditary bondsmen! know ye not,
Who would be *free, themselves must burst their bonds*."

Deeply grateful for the assistance you have given our cause,

I am, Sir, your very obedient Servant,
CHARLES F. J. LORD, Hon. Secretary.

THE PRIZES AT ST. THOMAS'S HOSPITAL.

[To the Editor of the Medical Times.]

SIR,—We, the undersigned, were appointed by our fellow-students as a Committee to draw up an answer to an anonymous attack which appeared in the *Lancet* for the 23rd June, directed against the Institution with which we are connected. We accordingly wrote to the Editor of that Journal, emphatically denying the allegations of his Correspondent, and requesting the insertion of our communication; its receipt was acknowledged in the following Number, but no further notice has been taken of it. That he should admit into his columns, and thus appear to countenance, the scurrilous and libellous communication which purports to come from a St. Thomas's Student is, to us, a matter of surprise and regret, and it is still more so, that, departing from the spirit of his motto "Audi alteram partem," he should close his columns to our reply.

The Author's intention evidently is to injure the school and wound the feelings of the gentlemen connected with it.

In the first place, he strives to convey the impression that, owing to the friendship of Mr. Whitfield, the prizes were unjustly awarded to Mr. Money; and states, that he had reason to know beforehand to whom they would be adjudicated; and, to give his accusations the appearance of truth, acquaints us with his respect for that gentleman's talents and industry, and presents us with a copy of one of the examination papers, and informs us that he himself is an interested party.

The first statement is altogether incorrect. Previous to October last, Mr. Money and Mr. Whitfield were totally unacquainted with each other, and since that period the latter gentleman has enjoyed no more of Mr. Whitfield's friendship than every industrious student is likely to obtain.

The assertion that the prizes were unjustly awarded, and that the writer had a foreknowledge of the result, no gentleman can possibly believe. Surely the fair fame of the adjudicators is not to be tarnished by the imputations of any anonymous calumniator. The gentlemen alluded to are Drs. Leeson and Bennett, and Messrs. Le Gros Clark and Taylor, to whom must be added, as being on the Committee of Lecturers, Dr. Butler and Messrs. F. H. Green and Grainger, gentlemen whose moral worth is unquestioned and unquestionable.

The assertion that there were three questions only in each subject is equally incorrect, there being six in Materia Medica, Chemistry, and Anatomy severally.

The paragraphs concerning clinical lectures and clinical clerkships are false. The former have been given since November last, with scarcely a week's intermission; and the latter are only neglected by those ignorant of their value.

The remainder of the letter is so manifestly an attempt to injure and annoy the gentlemen who are mentioned, that we shall not condescend to reply to it.

In conclusion, Sir, we may state, that had the author endeavoured to improve what was amiss, and to eradicate what was wrong, we should never have risen in a body to deny our participation in his sentiments.

To root out error and reform abuses, though unpalatable to some, is a part that all must applaud; but under its semblance, anonymously, without an attempt at supporting the accusation, to undermine the character, and blacken the reputation of those who are unsullied by the breath of slander, or the imputation of dishonour, is an action at once ungentlemanly, cowardly, and villanous.

J. S. BRISTOWE.
LEONARD W. SEDGWICK.
CHARLES O'CALLOGHAN.
JULIUS WILES.

St. Thomas's Hospital, July 17, 1849.

MR. SKEY ON THE TREATMENT OF CHRONIC ULCERS WITH OPIUM.

[To the Editor of the Medical Times.]

SIR,—Some months since I was informed that an assault had been made by a Mr. Critchett on a somewhat favourite doctrine of mine, relative to the influence of opium in promoting the growth of healthy granulations.

In your last Number I learn that he has written a book on ulcers, advocating the old story of "supporting the vessels"—*more* Baynton and a host of followers down to Mr. Critchett.

With that part of his work I have nothing more to say, beyond the simple expression of my opinion, that to talk of *supporting the vessels* is unphysiological, and that *support* is not the principle on which good is effected. Here, at starting, then, it is my misfortune to differ from the author of the work on ulcers; but, however I regret the difference, I prefer the

candid acknowledgment of my dissent to the adoption of any mean, truckling, or indirect endeavour to impress the world at large with the idea that I am buying Mr. Critchett's favour and advocacy at the expense of truth; and I do trust that my professional character for independence is yet unstained.

Mr. Critchett finds no favour, in my opium doctrine, on which it is my misfortune again to differ from the author of the work on ulcers. As my opinions on this subject have been before the world some dozen years or more, and Mr. Critchett's opinions have been recently published, perhaps I might in justice claim the right to suggest that Mr. Critchett's opinions differ from mine rather than my opinion from his. However, I will not contest that point, but take it for granted, that your readers, if they have roused themselves to the level of the subject of our differences will naturally enough, after the decided expression of Mr. Critchett's disapprobation of my views place me on my defence.

Mr. Critchett asserts, that he, whom I take it for granted, has rendered himself master of the principle I advocate, viz., that the internal administration of opium will cause the growth of healthy granulations in a chronic ulcer, in which every other agent has hitherto failed,—Mr. Critchett, I say, asserts that he has tried the experiment in some thirty or forty cases, and *in no one instance has the result borne out my statement*,—in fact, that he has not only not seen the phenomenon I have described, but that he has seen that it does not occur. So that thus far Mr. Critchett is "competent, from his personal knowledge," to furnish not merely negative but positive evidence against me.

Now, as chronic ulcers are as plentiful as blackberries, and opium nearly as cheap; and, as I should be ashamed to do Mr. Critchett the wrong to suspect him ignorant of the character of a chronic ulcer, any more than I would shield myself from his attack, by acknowledging, in a cowardly way, that I, perhaps, was hardly *au fait* at chronic ulcer when I wrote my pamphlet; so it appears to me that an unintentional perversion of truth must exist somewhere to explain the discrepancy between us two rival authorities—if I may take the liberty to use the term "us."

However, my reply to Mr. Critchett is contained in the facts of the following case:—

In the summer of last year Mr. P., a gentleman residing in Montagu-square, a Governor of St. Bartholomew's Hospital, placed himself under my charge, (Mr. Critchett's book not having then been published,) with a large chronic ulcer on the calf of the right leg. Its margin was irregular and jagged, and was elevated at least one-third of an inch above the base of the ulcer, which base was hale and bloodless. This wound was about the size of a man's extended hand, including the fingers, or even larger. It had existed for, I think, seventeen years. All remedies had failed, and the cure had long been abandoned as hopeless.

I gave Mr. P. half a grain of opium night and morning. In three days he himself noticed the singular red colour of the entire margin of the ulcer, which in a week extended over the base. I rolled and strapped the limb; the entire sore consequent on its depressed surface being placed beyond the influence of the pressure.

Within two months that sore was reduced *to the size of half-a-crown*, and the *only remedy employed was half a grain of opium night amd morning*, which, by-the-bye, had a very beneficial influence on his health.

If any statement of this case be deemed insufficient, I will produce Mr. P. in court immediately on his return from St. Petersburgh, and he shall give his version both of the disease and of the cure, and I fancy he might do so not altogether unprofitably.

I cannot comprehend how any man of ordinary observation can be blind to the notorious influence of this valuable agent in the treatment of chronic ulcers of any description.

I have myself treated, I may say, hundreds of cases. I hear of its success on the Continent, I hear of it in the United States and Canada, and I know it has been successfully employed in Calcutta.

My pamphlet was translated into French shortly after its publication in 1834, by M. Mayor, of Lausanne, a gentleman of no mean pretension to professional repute, who, in a letter he wrote me, says, that "he was delighted with the principle, and should adopt it on every occasion where practicable."

My own field of observation has not been small, and I have, notwithstanding the denunciations of Mr. Critchett, adopted it uniformly for some eight years in the out-patient room at St. Bartholomew's Hospital, where an average of about 300 weekly patients furnishes me with occasional examples of chronic ulceration of the extremities.

Mr. Critchett's argument is put forth in so knock-me-down and off-hand a style that I really hesitate even now in believing that I have answered it. I confess I am desirous of wresting that small portion of the Surgical reputation of St. Bartholomew's Hospital that hangs on me from the contempt to which Mr. Critchett's criticisms would consign it; and if I knew in what direction to appeal for the returning confidence of the Profession, I would instantly move in the same.

The truth is, that I do not carry these ulcers about with me, but they are to be found at St. Bartholomew's Hospital, I know; and I could have imagined that hospitals down in the far east, as the Yankees say, had been not altogether without them.

Finally, Sir, I will barter my entire professional reputation against any such small portion of the reputation of Mr. Critchett as he thinks will balance it in value—that the indiscreet publication of his want of knowledge will, in the end, do good service to the cause he has so unhesitatingly denounced, and, indeed, I am not quite sure that such is not his own secret intention.

I am, Sir,

Your very obedient servant,

F. C. Skey.

Lower Grosvenor-street, July 16, 1849.

THE SKIN CONTROVERSY. BRANDY AND SALT IN SKIN COMPLAINTS.

[To the Editor of the Medical Times.]

Sir,—This is certainly the age of Brass, Nostrums, and Specifics; for no Practitioner seems complete, when starting in life, without a "specific" for one or all complaints that flesh is heir to. Now, Sir, although I have myself no faith whatever in "universal remedies," because they appear to me alike at variance with the principles of science, honesty, and common sense, still there is a remedy for skin complaints which I have found to be attended with such surprising success, that I wish to communicate it, through your pages, to the Profession, and that remedy is simply—Brandy and Salt.

The reader may, perhaps, smile at the ingredients; but for that I care little,—Galileo was smiled at first, and persecuted afterwards,—for I know that I am conferring a boon upon the Profession, and on suffering humanity, which will be duly appreciated in time. I have tried all the usual skin remedies, including arsenic, cantharides, corrosive sublimate, prussic acid, oxalic acid, internally; and fumigations, lotions, and ointments of all kinds, externally. The result is, that I failed oftener than I succeeded; and in two cases the patient had a narrow escape.

I have no wish to enter the lists with such able Practitioners as Messrs. Innis, Walker, and Hunt; but it appears to me, the error these gentlemen fall into is in recommending the same remedy for a variety of complaints quite opposite in their nature; and nothing can be more empirical than that of attempting to cure a constitutional disease by local applications, in whatever form they may be administered. I, therefore, think the merit of those remedies exaggerated.

From a consideration of all those circumstances, and an anxious desire to assist, however humbly, in rescuing this branch of the Profession from the quacks, into whose hands it is fast falling, I have, for several years past, devoted my best attention to an experimental inquiry into the nature and treatment of skin complaints. I have ample opportunity here for studying those diseases in every shape and form, for I will back Gravesend against any town of its size for cutaneous eruptions. It is not the fault of the climate, for a healthier place there cannot be; but it is entirely owing to the gorging, cramming, and guzzling propensities of the cockney visitors in the summer. My patients invariably commence the instant they leave London-bridge, and, during the entire voyage, men, women, and children, indiscriminately seem eating for a wager. To consume the greatest quantity of stuff in the shortest possible space of time, seems to them the *summum bonum* of life. The swing, rocking-horse, and merry-go-round, on Windmill-hill, completes the business. The young ones, if they escape convulsions, are sure to take the pip; and the old ones the surfeit, or some other cutaneous abomination.

These, Sir, are the kind of patients I have to deal with, and my practice is this: As soon as they fairly sicken, (which is generally the day following the churning at Windmill Hill, for by this time all the humours are vitiated and in an acrid state,) I immediately prescribe four ounces of common salt, dissolved in a pint of brandy, twenty-five over proof, two ounces to be taken every half-hour until it produces such a fermentation in the blood, that all the vicious humours are destroyed by a species of internal combustion, or else driven out of the body by force of the internal heat. Sometimes the skin becomes as red as a boiled lobster, but this is a good sign; for once I get the enemy into that condition and situation, I soon reduce him by heroic doses of sulphur and cream of tartar There is no danger of killing or poisoning the patient by my plan.

I am not one of those who are always crying out "There is nothing like leather!" but I think a rational treatment like mine, based as it is on scientific principles, is entitled to take precedence over a host of those puffing nostrums which are so much in fashion just now. At all events, I can challenge competition with any other skin practitioner. My remedy is not recommended for all and sundry diseases of the skin, and, therefore, has no pretensions to be a "universal remedy." Its beneficial effects are confined to one section of those complaints, being chiefly developed in the Gravesend eruptions.

Now, Sir, it appears to me, that all diseases are not alike in all places; but whether it is the difference of climate or mode of living, that causes the variation, I cannot pretend to say. However, I am of opinion that the science of skin diseases and all other cutaneous affections, can be materially advanced by a division of labour. For example, if Mr. Innis were to confine himself to the radius of a mile from St. Giles's; Mr. Hunt to Herne Bay, from the Lower Reach to North Foreland; and myself to Gravesend, including Rosherville and Tivoli, I think, Sir, that by comparing notes, after due experience, we might produce something beyond all risk of reproach for quackery or hasty conclusions. But as the subject now stands, it appears to me to approach nearer to the science of humbug than to any branch of a legitimate science, and that every nostrum has its turn as every dog has his day.

From this view, however, I would exclude my own method, because it is based on scientific principles, has no pretension to be a universal remedy, and is peculiarly suited to the idiosyncrasies of my patients, as well as to the *genius loci* where it is prescribed.

I am, Sir, your obedient servant,

J. O. Brown.

Gravesend, July 10, 1849.

P.S. I have a work in the Press, giving a detailed explanation of my views and treatment, with numerous cases, which I hope soon to have the pleasure of forwarding to you.—J. O. B.

[We owe thanks to our unknown Correspondent for the shaft of ridicule he has launched against the host of skin doctors, who like locusts cover the land. These people have really become a pest to the respectable members of the Profession. One displays, to catch the eye, a series of drawings of elegant ladies and gentlemen, only rendered more attractive by their afflictions, and hopes by these pretty pictures to *draw* the public gently to himself; another seeks to affright the sufferers by hideous representations (skin bogies) of what they may become if they neglect to consult him; and when mamma's eye rests on her cherub Charlie, "the curly-headed boy," and then glances at the frightful figure which she is told he may one day resemble, she is *driven* to apply to *the* man who says he can avert the threatened evil. Another, still more culpable, strives, by loud shouting, to fix the attention of the people. Thus each, the representative of a class, stands, with his "little book of nonsense" in one hand, and his big bottle of specific in the other, calling to the gullible public, as the cook did to the ducks, "Come and be killed, come and be killed." The simple folk, hearing the loud shouting, and very imperfectly comprehending the language used, and seeing the book and the bottle, throng the doors of the impostor, and are fleeced as they deserve.—Ed. *Medical Times.*]

NITRATE OF SILVER IN QUINSEY.

[To the Editor of the Medical Times.]

Sir,—I shall feel obliged by your inserting the following remarks on quinsey, the treatment of which disease has hitherto been doubtful and unsatisfactory in the extreme, leeches, gargles, scarifications, and all the usual plans so abundantly recommended by both ancient and modern authors having been tried over and over again, with such uncertain power, that the chances of preventing suppuration were mostly hopeless. It is now five years since I adopted my present mode of treatment, and with unerring success. It is simply to apply a strong solution of nitrate of silver, 40 gr. to ℥i., by means of a large camel-hair brush, taking care to touch every part of the inflamed surface. This I repeat every eight or twelve

hours, seldom having occasion for more than two applications: an aperient had better be given at the same time.

So certain is the cure, that I never hesitate to assure my patient that the disease is quite in my power, and cannot, by any possibility, increase. I have never, since I first commenced this plan, seen a tonsil suppurate, and I use it in all stages, and often when suppuration seems inevitable.*

The first case in which I used it was a Mr. M——s, in this town, who had had quinsey before, with suppuration, and, dreading a similar result, he earnestly entreated me to try and prevent it, if I possibly could. I succeeded—much to his delight—and four times since it has returned, and as often been arrested. Once when, being out of town, (two years ago,) another surgeon was called in, and on my patient telling him the remedy with which I always stayed it, he immediately took out his caustic case, and so freely used it, that a second application was not required. I am induced to give this *never-failing* remedy additional publicity. I say *additional*, because Dr. Corfe has already spoken so highly of it in his invaluable portraits of diseases as having been first used in the Middlesex by Dr. Hawkins, in whose hands it has always been successful. I do not publish the result of my practice with any idea of claiming "priority." I know not how long Dr. Hawkins has used it; and, indeed, should not have known it at all had not Dr. Corfe given it to the world in the before-mentioned admirable paper. I truly hope that every practitioner who may see this report will give it a fair trial; indeed, no one is justified in withholding from his patient such a certain means of escape from a painful malady;—*one trial* I claim.

I remain, Sir, yours obediently,

Haverfordwest, July 14, 1849. J. D. Brown.

BOILED GROUND RICE AND BRANDY A VALUABLE DIET FOR ARRESTING VOMITING.

[To the Editor of the Medical Times.]

Sir,—It may not be generally known that ground rice boiled with water*, and a tablespoonful or two of brandy afterwards, added with a little sugar, is capable of arresting perpetual vomiting; I have known it taken with success when other remedial agents have failed. A teaspoonful of the rice thus prepared should be taken, and, if rejected, a second or third must be followed immediately after, when the desired effect will be produced. The patient must be kept upon this diet for a few days, avoiding every other article of food. I have never known the rice diet used in cases of cholera; but I am of opinion it may be found useful in the primary stage of the disease when vomiting commences.

If you consider this hint worth the attention of your readers at this particular period, you will oblige by allowing a small space in the *Medical Times*.

I am, Sir, your obedient servant,

July 14, 1849. H. O.

MEDICAL EDUCATION.

[To the Editor of the Medical Times.]

Sir,—There are so many grievances connected with the Profession apparent to me, that with your permission I will from time to time draw the attention of your readers to a few observations which I propose to make on them. It being best to begin with the foundation on all occasions my first hits will be on the subject of Medical Education. Having been a student I may, of course, be expected to know something of the matter; and, now that the period of my studentship has long since passed, I have had time to consider whether the views I entertained in my pupilage are at all approaching to truth.

A correspondent in your Journal (more metaphysical than myself), some time ago, gave his opinions on this matter; but whether what he said had any effect, or is likely to have, I am unable to speak.† Your Correspondent asked the following questions:—"First. What preliminary education, moral and intellectual, is most suitable? A full answer to this question would take up too much space, but it may be just necessary to remark, that as regards morality and intellectual acquirements, youths intended for the Profession ought not by any means to be short. The first ought to be inculcated by parents, the second may be partly instilled by parents, but chiefly by the teachers under whom they are placed. I might considerably dilate on the defective system of educating youths at the present day; but I shall be brief. First. I would contend that children are put too early to school. A child of mine should not go to school before it was eight or nine years of age. Its strength is required before that age for growth. Books before then are a burden, and are seldom understood. The first three years after the age I have named ought to be devoted to the study of plain English, and, after that period, the line of study ought to consist of languages and some of the sciences.

The method of teaching is greatly defective. Pupils ought to be made to understand by the teacher himself explaining; for at present they are left to overcome every difficulty by "their own sharpness," and, if they do not succeed, as few do, all that they get is a good thrashing with the horsewhip. I, for my part, when at school, felt the ill effects of this system, and, I am sorry to say, suffer from it at present, as doubtless many others.

A youth is unable to gain a proper knowledge of the languages and different matters in his preliminary education before he is seventeen, unless he be extraordinarily quick. I would say, therefore, that it ought to be made a rule that no one ought to enter the Profession under that age, and that he be kept at school till then.

Second. "What kind of education is most suitable, preparatory to engaging in the practice of our Profession?"

In order to divest all subsequent fear from the minds of students, I think that they ought to undergo a classical examination before they commence the study of any subject connected with the Profession. Having obtained a certificate to this effect, the next thing to be taken into consideration is an apprenticeship. I, with many others, am, however, averse to a five year's apprenticeship. But I think a short one of two years would be sufficient, with a view of learning the nature of drugs and the compounding of medicines. A certificate of moral character and diligence may then be given by the master, if the pupil is deserving. Without this certificate he ought not to be allowed to attend lectures or hospital practice. In a subsequent letter I propose to show that it would be the best to give up dispensing to the chemists; surgeons, &c., prescribing and charging for advice only.

To some, such a plan may appear injurious to the Profession; but I think there are many reasons in favour. It would raise the respectability of the Profession; relieve it of being looked on as a trade. It would make the members of it less numerous. Though at first it would take away the emoluments obtained from apprenticeship fees, yet, from the circumstance of the Profession being less numerous, the emoluments would be made up by fees from patients.

These suggestions will derive strength in favour of adoption, when it is recollected that many enter the Profession who have never received scarcely any classical education, at all. Many cases I remember; and those persons who have succeeded under such circumstances have had considerable difficulties to contend with, in order to prepare for examination at the Hall, and that preparation is often of no utility, for the candidates are apt subsequently to forget all they have learned for the time. That this is the case with the majority, I will not pretend to say; I do not believe it is; but, at the same time, it is necessary that all who are in the Profession be known to possess classical knowledge, and that their general education has been sound. As respects the recent improvements made in the curricula of the College and Hall, I do not hesitate to say, that they are far better than formerly. When I was a student, it was impossible for me to attend to all the subjects at once. The first year I was obliged to neglect both anatomy and physiology in order to learn materia medica and chemistry. The second year I studied anatomy, physiology, and a little midwifery; the third year, anatomy, surgery, and practice of physic. The summer session, of course, I had more time to study the subjects prescribed. When, however, I had concluded my studentship, though I had studied several hours a-day for the whole period of three years, I was lamentably deficient, though I cannot but acknowledge I had learned a great deal, and was looked on by many of my fellow-students as knowing something, *i. e.*, not altogether ignorant of my profession. With the regulations as at present prescribed, I think it would be advantageous to add the study of comparative anatomy and natural history in the second summer. With a view, however, of amending the present regulations, it would be advantageous for the student to attend the materia medica and chemistry lectures during the time of apprenticeship, which I name to last two years. Such a plan would enable the student to devote more time to the study of the subjects prescribed, as well as a few others which might be added. My plan I will give in a tabular form, that it may be better understood:—

Periods for Attendance on Lectures.	Subjects.
Period of Apprenticeship.	Natural Philosophy, two Courses on Materia Medica and Chemistry, Theoretical and Practical.
First Summer Session	Botany, Natural History, Midwifery.
First Winter Session	Anatomy, Physiology.
Second Summer Session	Midwifery, Comparative Anatomy.
Second Winter Session ..	Anatomy, Physiology, Surgery, and Practice of Physic.
Third Summer Session ..	Toxicology, Medical Jurisprudence, and Psychology.
Third Winter Session....	Anatomy, Physiology, Surgery, and Practice of Physic.

Thus it will be seen by extending the time for study from three years to five, a great advantage would be gained, and more subjects might be included in the regulations.

Attendance at the hospitals might remain as at present; but it ought to be a regulation, that courses of lectures be delivered on clinical medicine and surgery, and that each pupil be required to dress cases under the superintendence of the visiting surgeon.

As respects the system of prize-giving, I must confess I have considerable objection. I do not know that it is of any practical utility, it being well-known that many who gain such honours are not always deserving. It is likely to engender a false degree of pride, besides not unfrequently causes unpleasantness among the students themselves. In subsequent years, they are little thought of. As respects certificates of honour being awarded to the most diligent and deserving pupils, I think that they might be continued with advantage, as they are likely to prove the best passports to future success, with a good knowledge of the Profession.

I have now given a number of propositions for the consideration of your readers, which, I think, might be readily agreed to and adopted. I have not undertaken to defend all my arguments, as, by so doing, I should take up too much of your valuable space. I trust, therefore, no defence will be required. Taking leave of you for the present,

I am, Sir, yours respectfully,

A Reformer of Abuses.

[We so far agree with a "Reformer of Abuses," that we think some improvement might be made in the regulations of the Medical Corporations—the present Parliamentary law respecting our Profession even remaining unaltered. Few, we think, besides our Correspondent, could be found to advocate an apprenticeship for two years, to be served in a chemist's shop. Moreover, the repeal of the Apothecaries' Act, and the establishment of a new Medical Institution, would be required before his suggestions could be carried into effect. We hope to be able to recur to this important subject next week.—Ed. *Medical Times*.]

MEDICAL RELIEF OF THE POOR.

[To the Editor of the Medical Times.]

Sir,—Some time ago, the newspapers reported a painful case of destitution and suffering, which had failed to obtain proper attention from the parish authorities and which called forth the following unjust and injudicious comment, addressed to the Editor of a periodical publication:—

"Sir,—Is it not enough to make one's heart bleed for the poor and miserable people of this country, when they are subject to the hard-hearted mercy of man, similar to that reported in the *Times*? 'This is an evil under the sun.' Whence does it spring? To what source may this murderous system be traced? One Surgeon will not act,—another will not act,—in the greatest hour of need. In every other business competition is allowed; but, in the Medical Profession, the laws of the land interfere with the wants and supply of the people, and, consequently, the people have to pay for the monopoly thus raised, and, at the same time, suffer the evil effects of that monopoly in physical suffering. Were the laws respecting medicine entirely repealed, the people have sufficient judgment to know where to apply in time of need;

* Milk must not be used on account of its turning acid.

† *Medical Times*, April 22, 1848.

and, not only so, the law of nature (the love of one's own life) would lead them to obtain medical relief from the right sources,—and surely men of knowledge, reputation, and experience, would not suffer from such an alteration: nor is it likely men will cease to acquire knowledge for the attainment of usefulness towards mankind. Until all medical laws are cancelled, suffering and privation will be endured by the poor; for it is upon them the iniquitous system presses most heavily. In one Union, close at hand, they only grant *loans* for medical relief, to be repayed out of their wages after recovery. Could we inquire into the working of the system, what misery would meet the eye! Shall the poor of England always suffer?

"Yours, obligingly,
"A FRIEND TO THE POOR."

Is our "obliging" friend in jest or in earnest, when he recommends the abolition of all medical laws? He is certainly joking, when he says, "Were the laws respecting medicine entirely repealed, the people (would) have sufficient judgment to know where to apply in time of need." The "judgment" of people in medical cases. For illustrations of it, look to the sale of quack medicines, which are advertised to cure all kinds of incurable complaints, and to remove all sorts of irremovable symptoms. Look to the popularity of ignorant empirics, and illiterate "bone-setters," and female professors of physic. Not long ago I heard a self-constituted physician in petticoats recommend "a dose of castor-oil," as it would "grease the nerves." Look, also, at the resort for medical advice to chemists; whose business is, not to *prescribe* medicines, but to *compound* them; who have seldom attended any lectures but those on Chemistry, or read any professional books except the Pharmacopœia; who, of course, prescribe for symptoms, though they may arise from opposite causes, with whom headach, for instance, is *headach*; whether inflammatory, rheumatic, or nervous; whether arising from too *great* a supply of blood to the brain, or too *little*; or from sympathy with the stomach, or some other organ. Does our "friend" seriously propose to hand us over to the tender mercies of every self-dubbed "doctor", who may choose to put a brass-plate on his door, or a coloured bottle in his window? He is certainly not serious when he talks about "monopoly," while medical Practitioners so abound in every corner of the land, as to be eating each other up. If he resides in some fortunate spot where doctors are not more numerous than patients, he has only to publish the name of that El Dorado; and he may depend on a whole cargo of Hall—and College—gentlemen, by an express train. He is also very facetious, or very ignorant,—I will take for granted the former,—when he talks about want of "competition" among medical men. Want of competition! What, but *excess* of competition induces a medical man to contract for attending many thousand paupers, at so many pence per head, and scattered more miles than he can well gallop over? "In every other business competition is allowed." Indeed! Have clergymen, and lawyers, and naval officers, no examination to undergo? Are our limbs and our lives to be less carefully guarded than our legal rights? "Were the laws respecting medicine entirely repealed, the law of nature (the love of one's own life), would lead people to obtain medical relief from the right sources." What has "the love of life" to do with judging of a doctor's skill? And how do "medical laws" interfere with it? What the law requires is, that the poor shall not be committed to the care of any man who has not given proof of his competency, by passing an examination before a Medical Board. Were this check abolished, how loud would be the outcry against trusting the poor to incompetent pretenders! The case alluded to was sufficiently painful; but our "obliging" friend's remarks on "the *hard-hearted mercy* of man, similar to that reported in the *Times* (a curious kind of "mercy" to be *reported* indeed!) are quite beside the mark. So far as appeared from the newspapers—and I know nothing of the case from any other source—the conduct of the medical men was not in question at all. The gentleman whose duty it was to attend, does not appear to have known that his services were required. No doubt he would have rendered them had he received proper intimation, which the Relieving Officer ought to have sent. As to the other medical man, having already (in the shape of Poor-rates) paid his quota towards providing proper attendance for the poor woman, it would have been unreasonable to exact his time and skill (which are his stock-in-trade) into the bargain, unless the proper medical officer had been out of the way. In cases of emergency, medical men have never been found backward; but they are the only persons expected to serve the public for nothing.

"In one Union, they only grant *loans* for medical relief, to be repayed out of *their* [*the*] wages, after recovery." A most excellent plan! What right-minded poor man, in the receipt of wages, would not rather pay his own expenses, by easy instalments, than be indebted to the hand of charity? Are the poor to be degraded into paupers? Does their "friend" wish his *protegés* to become parish mendicants? Ought we not to regard their principles as well as their pockets?

But what is our Solomon's remedy for the neglect of a relieving officer, and the evils of pauperism? "Until all medical laws are cancelled, suffering and privation will be endured by the poor." This, then, is his panacea: "Cancel all medical laws." Do away with all tests of qualification, and commit the broken bones of the poor to men who never studied anatomy; and let them be bled by "barber surgeons," who know not the difference between an artery and a vein. This is the profoundly sapient regulation, at which suffering and privation are to take their everlasting flight! Well may the poor exclaim, "Save us from our *friends!*"

"Shall the poor always suffer?" More or less, it is to be feared, poverty will always be attended with suffering; but any reasonable plan for its mitigation ought to be adopted. Several millions are devoted to that object every year. I hope "a friend to the poor" never grumbles at the poor-rates! "The public have to pay for that monopoly." To those who know the miserable pittance dealt out to Union surgeons, this talk of payment is simp[illegible] If our "friend" will "obligingly exert [illegible] to procure for the poor a sufficient number of medical attendants, at a sufficient salary, he will prove his friendship to the poor, and "oblige" his readers much more effectually than by writing incoherent letters on a wrong scent.

I would not be understood to deny, that the machinery at present in use may require alteration. The suffering poor ought not to be dependent on the caprice of a relieving officer. Medical men, when they see occasion, should be allowed to act, and to charge the expense to the parish or Union.

There is another measure, which, though it would not provide for unforeseen contingencies or unavoidable misfortunes, would greatly lessen the number of the poor, and the amount of their suffering. At this plan I will venture to hint, though at the risk of being denounced as a hard-hearted political economist. *Let no one plunge into the expenses of a family, unless with a fair prospect of paying his way.* I remember attending (gratuitously) a woman in her first confinement, and in circumstances of great destitution. On inquiry she confessed that, on the day of their marriage, they "had not money enough to buy a supper."

Not a fortnight ago, a young woman applied to a medical charity, on account of a sick husband, who had been out of work *four months*, and to whom she had been married *three weeks*. At present they are living on their parents; when the latter are tired, they must come on the poor-rates. In due time, no doubt,—should it be with the husband in months to come, as it has been in months that are past,—the parish will have to pay a surgeon for helping into the world an additional little mouth, and all three must be supplied with food in health, and physic in sickness, at the expense of "their friends and the public in general." "Shall the *poor rate-payers* of England always suffer?"

N. ROGERS, M.D.

UNIVERSITY DEGREES.

[To the Editor of the Medical Times.]

SIR,—It is a pity that the gentleman whose letter, under the above heading, appears in the *Medical Times* of this week, did not learn something more accurately about the British Universities, and understand his subject better before he sat down to "make remarks" for the guidance of general Practitioners about to take the title of M.D.

It is quite true for him, however, that Oxford and Cambridge are closed against the sudden elevation of such aspirants to the "*highest honours of the Profession.*"

The expenses of the education, or the length of time in residence in those Universities, do not form so great a barrier to the taking of medical degrees there as the gentleman seems to imagine; and, as I believe that he partakes of an ignorance upon this subject that is very prevalent in society, with respect to the system and expense of education in the English Universities, I would avail myself, with your permission, of this opportunity to set him and many of your readers right in that respect.

The expenses of education in Oxford and Cambridge, so far as the College and University fees go, are very moderate indeed; much more so than in many of our private, and than in any of the public schools. With respect to the education, let us say at Cambridge, for the degree of M.B., it is very limited, and costs but little; and, as to time there, the student may *go out* in medicine within three years. To *go out* in medicine, or in law, is what is called, in the University, *degrading*, the degree being inferior to the A.B. degree. To go out in medicine, for instance, the student has no occasion whatever for any knowledge of mathematics or physics, and the only examination, of a preliminary nature, that he passes in the University, is that called the *Little-go*, or previous examination, which is held in the second March after going into residence.

This examination consists simply in translating passages in Latin and Greek books, and the students have notice of the subjects twelve months before the examination comes on. That is the only test of classical attainment that the candidate for the degree of M.B. need undergo; and that, I can assure you, Sir, is not very trying.

Thus, as to the examination for the medical degree, he has to do but with one examiner, the Regius Professor of Medicine,—a circumstance which, in itself, stamps the value of the degree as a testimonial entitling the holder to the confidence of the public as a Medical Practitioner. This, however, is, in the estimation of your correspondent, the *beau ideal* of a Medical degree; but the dear gentleman was not in the secret; he knew nothing about it, and, with the dust in his eyes, ranked it above the degree of his own *Alma Mater*.

"The University of London," he says, "takes its place next (to Oxford and Cambridge) in consequence of the *difficulty of its examinations.*" Here is an inconsistency, for he awards the first rank to the degree that is got, I may say, without any examination at all, or, at least, that which *one man*, perhaps a clever man, perhaps a heavy, old, stupid man, conducts and institutes; for, be it recollected, that a Regius Professorship is not always given to the brightest light of the Profession. It is very well known, that, with the M.D. degree thus got, the holder has the legal right to practise as a *Doctor* in every part of England, except within the precincts of the University, and in and within seven miles of London, where the College of Physicians has jurisdiction. Upon ten years' standing, the Bachelor takes his degree of Doctor as a matter of course on *paying for it*, as there is nothing for nothing in Universities. He has not, however, to undergo any further examination or any trial beyond a laughable monkish ceremony, descended from the mediæval customs.

Now, accompanying our author step by step, we come to the University of Edinburgh, long famed as the most renowned school of medicine in Great Britain, and the *Alma Mata* of the greatest number of the greatest physicians and medical philosophers that have adorned the Profession and enriched its sciences. Edinburgh, however, is in bad odour with your Correspondent, the principal object of whose letter would appear to be to run down that great university, and elevate, at its expense, Aberdeen and St. Andrews.

I do not presume to come forward as the champion of that seat of medical learning and philosophy. It wants no such aid; nor is it necessary, at all events on the present occasion. Your Correspondent, if honest, is as ignorant of the nature of the system of education at Edinburgh as he is of that at Cambridge or at Oxford; he would make your readers believe, that, upon *one* year's residence, the degree of M.D. may be taken in Edinburgh. This is a gross misrepresentation, made, no doubt, in the absence of accurate knowledge on the subject, and, perhaps, upon some incredible hearsay evidence.

The University of Edinburgh requires from candidates for the degree of M.D. proofs of having devoted *four whole years* to the exclusive study of medicine, one year of which may be passed in a private school of reputation. The other three years must be passed in one or more universities having a regularly organised Faculty of Medicine. One of these three years must be passed in Edinburgh, which is a very salutary regulation.

Then, as to the examinations, it is to be recollected that they are arranged as to subjects and extent by a numerous body of Professors, of European reputation. These examinations are wisely adapted to the existing state of science and to the wants of the public for medical attendants of the highest order.

The candidate for the degree has to pass through the hands of thirteen Examiners, each a Professor, in the habit of teaching, and accustomed to see at a glance the mental qualities of the respondent. Great discretion must necessarily be used by such a body of men in granting the degree or rejecting the candidate. In the exercise of such a discretion, men of but slender mental endowments are allowed to pass through and get degrees in every university; and possibly, some men have the M.D. degree of Edinburgh who may have appeared as "fools" in the eyes of your learned and erudite Correspondent. Between the first wrangler in Cambridge and the last man in the *poll* there is an immeasurable distance in point of mental power and attainments; yet they are both of the same degree in the university,—both Bachelors of Arts. It would not do to reject the last man in the *poll* because he was not on a par in knowledge with the first wrangler, or even with the man next above him. The Examiners in all universities settle upon a minimum amount of attainment for the degree and that must be adapted to the powers of men of ordinary mental capacity and industry.

Thus, as to Glasgow, Aberdeen, and St. Andrews. Your Correspondent evidently knows but little about these Universities. Glasgow is a complete, well-organized University, and has always sustained a high character. It is, however, easier to get the degree of M.D. at Glasgow than at Edinburgh; and it is no uncommon thing for gentlemen plucked in the latter University, to go to Glasgow, Aberdeen, or St. Andrew's, and pass without delay or difficulty. Notwithstanding what your Correspondent says, Aberdeen is a truant in granting degrees. Even according to what he himself states, every *Apothecary* or *General Practitioner, of five years' standing*, is eligible for the degree there; and when a University opens its doors in that way to grant degrees to strangers, not its own alumni, *it is all in my eye* to say that the examinations are stringent, or at all calculated to puzzle or perplex the man who has come with his money to buy an M.D. degree.

St. Andrew's is a decayed University, an old trader in degrees. All sorts of quacks used to get degrees at St. Andrews without even showing themselves there. Since the late reformations in that University and at Aberdeen, the candidate for the degree must pass an examination. The Examiners are chiefly practitioners in Edinburgh, who are paid for going to St. Andrew's, at stated periods, to examine *and pass* the candidates. It is palpably a money-getting business, and the Examiners know better than to reject the candidates, for doing so would be *refusing money*, a habit to which our friends in Scotland are not much addicted. There is, no doubt, a rivalry in the Scotch Universities. Glasgow undersells Edinburgh, and Aberdeen undersells Glasgow. St. Andrew's is the cheapest of all; and it is to St. Andrew's, therefore, that I would recommend those gentlemen who yearn for the title of Doctor to repair for the Degree. It is positively a better Degree as a testimonial of competency to practise than the Degree of Oxford or Cambridge, and as ninety-nine persons out of every hundred value the Doctor for something extrinsic of his diploma, the cheaper and easier he gets his title the better.

But, Sir, it is much to be lamented that this rivalry should exist,—that there is not uniformity of education and of examinations.

The question of Medical Reform is one, however, of too much difficulty, it appears, to be successfully grappled with by even a Minister of State.

Oxford, Cambridge, Aberdeen, and St. Andrew's, ought to be prohibited from granting Medical Degrees, because they have no, or insufficient, machinery for teaching or for examining. An exception, perhaps, may be claimed for Aberdeen, because the population there is considerable, with a large Hospital and two ancient Colleges.

But, as a School of Medicine, Aberdeen, with all her ancient *prestige*, is inferior to Bristol, Liverpool, Birmingham, Manchester, and other large towns. It would be better to limit the power of granting Degrees to the three Metropolitan Universities, London, Dublin, and Edinburgh, and to place them under the control of a Government Board of Public Instruction, that would enforce uniformity of education and of examination. The four Academies of France, each in itself a perfect University, are, in that way, under the management of a Board, with the Minister of Public Instruction at its head, forming, in the *ensemble*, the University of France. We can hardly hope for such a Medical Reform here, for, unfortunately, there is too much private interest concerned; and to propose any interference with Oxford or Cambridge would be fatal to any project; yet no project can be useful without depriving these two Universities of a power that they cannot exercise but injuriously.

I am, Sir,
Your Constant Reader,
M.D. ET CHIRURGUS.

London, July 8, 1849.

UNIVERSITY DEGREES.

[To the Editor of the Medical Times.]

SIR,—I can assure Dr. Lees, of Ashton-under-Lyne, that my only object in writing to you on the claims of the various British Universities, was not for the purpose of puffing St. Andrew's and disparaging Edinburgh, but to stimulate, in every way in my power, the present movement of graduating in some university by general practitioners. I have the interest of my class at heart, and know of nothing more likely to promote their respectability.

However, I have no doubt that the Profession will agree with me, when I say that a weaker reply to my remarks on Edinburgh could not be penned than that of the worthy Doctor's. Still, I like to see a man stand up for his *alma mater* to the best of his ability. There is, I believe, no second opinion as to the superiority of the London degree. In what particular point does it excel? Is it not in its examination? Yet Dr. Lees says examination is no test! Two men (brothers, perhaps) study at the same college, under the same Professors; one excels the other in intellect, in industry, and renders himself fit in every way for the practice of his profession; the other, on the contrary, is his opposite. Is it not by examination alone you can find the difference? Would you give both a merely nominal examination, and send them forth to the world, one to cure, the other to kill? Is it because Alison, Christison, and Syme, fill the Professors' Chairs with distinction, all their pupils must be first-rate men? that they can make the stupid man clever, the lazy man industrious, and a good physician of the man intended by nature for a ploughman? Sir, Dr. Lees and your humble correspondent are at issue; let the Profession decide. My argument is, that examination *alone* is the only true test of qualification. It is no reason, because a man has spent four years in Edinburgh, he must know his profession. I also assert, that the examination at Aberdeen particularly, but even at St. Andrew's, is a more difficult, a more respectable, and more practical one, than that of Edinburgh or Glasgow. I fully admit to Dr. Lees that there are good number of very clever men, both in town and provinces, graduates of Edinburgh, who are an ornament to their Profession; but it would be a frightful state of things if, amongst such a numerous body, there were not some who distinguished themselves from the bulk. One swallow does not make a summer. I have met, during my life, a vast number of the graduates of all those colleges, and I am bound to say, and I say it without envy or ill-will to any men, I found the graduates of Edinburgh and Glasgow *generally* possessed of inferior attainments. I have no doubt, before many years, the majority of the practitioners of the three kingdoms will be graduates of some university, and if the Colleges of Aberdeen and St. Andrew's continue to throw open their halls, as they now do, to the general practitioners, make their examination equal to that of London, and publish that examination as London does, they will rise in public estimation, and leave their competitors of Edinburgh and Glasgow where they deserve to be, far behind.

I remain, Sir,
Your obedient servant,
A CANDIDATE FOR THE DEGREE OF M.D. AT LONDON UNIVERSITY, AND M.R.C.S.

THE CHIEF BARON AND THE LAW OF LUNACY.

[To the Editor of the Medical Times.]

SIR,—There is an old proverb which is too often forgotten: it begins "*Ne sutor.*" The Chief Baron lays down the law. Well, but he goes rather further, and gives what we may hope is his own private opinion. His knowledge would not have been thought the less, if it had remained private; for it certainly is a very remarkable one. Only picture to yourself, Sir, the decrease in the number of lunatics! Talk of gaol delivery, what would it be to an asylum delivery! Let us just imagine the Chief Baron invested with authority to liberate those whom he considered ought not to be confined. We should probably find that some one who considered himself King of England, certainly not a dangerous hallucination, would, if liberated, not hesitate to endeavour to appropriate Buckingham Palace, or insult the Queen, and, if thwarted, may even go further. Or some man may, having the fancy that he is always cold, set fire to a farm stack to warm himself; another, who is under the delusion that he is very like a whale, may, although considered quite harmless to himself or others, on a sudden, endeavour to perfect the resemblance by going under water, and very probably remain there too long. But enough; instances without number may be given where persons, who are, to every appearance, "not dangerous to themselves or to others," being liberated, may, by any sudden provocation, become murderers or suicides. It is to be hoped that the Lord Chief Baron may recall this hasty expression before it is too late; or, if it is still his opinion, that he may be induced to modify it very much before we have another such a case as "Nottidge *versus* Ripley."

I am, Sir,
Your obedient servant,

July 14th, 1849. W.

MEDICAL NEWS.

APOTHECARIES' HALL.—Names of gentlemen who passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday, 12th July, 1849:—Robert Delafosse Shield, Clun, Salop; Alfred William Moore.

ROYAL COLLEGE OF SURGEONS.—The following gentlemen having undergone the necessary examinations for the diploma were admitted members of the College at the meeting of the Court of Examiners on the 13th inst.:—Messrs. Henry John Phillips, Kensington; Thomas Ellis, Balbriggan, county of Dublin; William Frederick Bassett, London; George King, Melksham, Wilts; Said Assaid, Syria; Charles James Morris, Glocester-terrace, Hyde-park; George Brown Turner, Horton, Gloucestershire; William Squire, Silsoe, Bedfordshire; George Hodson, Chester; William Hargreaves Manifold, Liverpool; George Anthony Kirsopp Lake, Teignmouth, Devon; Charles Henry Sinnock, Eastbourne, Sussex; and Henry William Hughes, Gawchmai, Anglesea. On the 16th inst.:—Messrs. John Albert Morris, St. James's-place; John Evelyn Crook, Northfleet, Kent; George Hymeneus Lovegrove, Gloucester; Thomas Arthur Finnimore, Harrow-road; William James Moore, Halesowen, Worcestershire; William Bradley, Preston, Lancashire; James William King, Dublin; Frederick Le Keur, London; and Philip William Govett, Plymouth.

THE FELLOWSHIP.—The Court of Examiners of the Royal College of Surgeons have just given notice of their intention to examine candidates for the Fellowship on Tuesday and Thursday, the 7th and 9th of August next; our advertisement columns will afford further information.

WAR OFFICE, July 13.—3rd Light Dragoons.—Assistant-Surgeon Vere Webb, from the 10th Foot, to be Assistant-Surgeon, vice Franklin, promoted on the Staff. 10th Foot.—Staff Assistant-Surgeon James Lewis Holloway to be Assistant-Surgeon, vice Webb, appointed to the 3rd Light Dragoons. Hospital Staff.—Staff-Surgeon of the Second-Class George Home to be Staff-Surgeon of the First-Class, vice James Moffit, M.D., who retires upon half pay; Assistant-Surgeon Henry Franklin, from the 3rd Light Dragoons, to be Staff-Surgeon of the Second-Class, vice Home, promoted; Acting Assistant-Surgeon John Duff, M.D., to be Staff Assistant-Surgeon, vice Holloway, appointed to the 10th Foot.

APPOINTMENT.—Mr. James Robinson has been appointed Surgeon-Dentist to His Royal Highness Prince Albert.

OBITUARY.—On the 12th instant, of rapid consumption, Mr. Maurice Dyte, of 44, Houndsditch, surgeon, in the 43rd year of his age.—At Southampton, on the 6th instant, aged 90, John Shadwell, Esq., M.D., Lord of the Manor of Horfield, near Bristol.

UNIVERSITY OF LONDON.—NEW CHARTER.—Her Majesty has granted to this University a new

Charter, which is likely to excite great interest and attention in the educational world. As our readers are doubtless aware, persons who have graduated for honours at Oxford and other Universities are sometimes compelled to refrain from taking a degree, owing to their conscientious objections to subscribe to the Thirty-nine Articles. By the new Charter, the Council will be empowered to confer the respective Degrees of Bachelor of Arts, Master of Arts, Bachelor of Laws, and Doctor of Laws on any persons who have graduated at Oxford, Cambridge, Durham, Trinity College, Dublin, or any other University in the kingdom. Another point in the new Charter which will be of great service, is that the Council may institute examinations for certificates of proficiency in any subject which they may think fit connected with the Sciences or Arts, such as Architecture, Civil Engineering, Chemistry, Botany, Geology, and Mineralogy; Zoology, Geography, Political and Physical, Navigation and Hydrography. The examination for certificates of proficiency was one of the original designs of the Council, which they were prevented from carrying out under the old charter.

Health of London during the week.—(From the Registrar-General's Return.)—The present return exhibits a serious increase in the mortality of London. The deaths, which in the previous week were 1070, have in the last amounted to 1369, and give an excess above the average of 361. This unfavourable result is produced by cholera and diarrhœa. The deaths from cholera were 339—more than double the mortality of the preceding week; those from diarrhœa and dysentery, which in the former week were 54, have rapidly increased to 100, which is more than in any corresponding week of five previous years. The total in the week from the three diseases is therefore 439, and makes an excess of 347 on the average of former years. The mortality from all other zymotic or epidemic diseases is 191, the average being 210; that from all sporadic diseases is 686, the average being 670. The progress of cholera in London is traced in the returns of the last six weeks, in which the numbers were successively 22, 42, 49, 124, 152, and 339; the progress of diarrhœa and dysentery in the same periods is shown as follows:—25, 38, 19, 33, 54, and 100. During these six weeks cholera was fatal to 425 males, and 303 females, of whom 387 died on the south side of the river, only 101 in the west and northern districts. Considerably more than one half of deaths from diarrhœa last week occurred under two years of age; whereas, of the 339 deaths from cholera, 192 occurred between the ages of 15 and 60. Last week 49 persons died of cholera in the district of Lambeth, 37 in Rotherhithe, and 23 in Bermondsey; but the epidemic now increases generally over the metropolitan districts. Hooping-cough, pneumonia, and phthisis are at present fatal to more than the usual number; the second, as well as the first, almost entirely to young persons. Typhus, measles, scarlatina, and smallpox are about the average, or fall considerably under it. Two men died of intemperance.

Sewers of the Metropolis.—Messrs. Austin and Smith, Consulting-Engineers and Assistant Surveyors to the Commissioners, have presented their Report:—

Belgrave-square.—These sewers are in a very unsatisfactory state, having above a foot of solid deposit. *Lowndes-place* has from one to two feet of deposit, (the smell is most horrible,) and the house-drains are nearly stopped. *Knightsbridge-green and Brompton-road* is in a dangerous state, and appears never to have been completed. From this manhole to the next, in the direction of Sloane-street, the deposit is so great, and the stench so strong, that one of the men came out in a fainting state.

Grosvenor-place.—This sewer, has from 9 to 14 inches of foul deposit. *Downing street* is nearly choked with filth.

Oxford-street.—The sewer on the north side, from Portman-street, westward, is in so ruinous a state as to be in danger of falling in; the arch is broken and depressed; the bottom full of steps and all kinds of inequalities, so that the sewer must be choked with deposit before it can have any discharge.

Whitehall-place has two or three feet depth of filthy deposit. *St. George's-square* has from one to two feet of putrid matter. *Pimlico-road* has deposit all along it, and in the immediate neighbourhood of Buckingham-palace this is 20 inches deep.

Upper and Lower Berkeley-street and Portman-square, North.—These sewers are in a ruinous condition, the side walls and crown having fallen in in various places. The invert is forced up, so that the breadth is only 9 inches where it was formerly 3 feet, and, for a distance of 1035 feet, the walls are abutting one against the other, and the arch without support for distances of 20 to 30 feet in length, and sometimes held up by a mere brick. Should this give way, the road will instantly follow. There is a deposit of 9 inches to 2 feet of rotten bricks, and so choked up that part of it could not be levelled. *Bryanstone-square.*—The arch of the sewer is in a very dangerous condition. In *Cavendish square* the sewer is very much decayed. In *Manchester-square* it is in a very dangerous condition.

Molyneux-street.—The lower part of this sewer is in danger of falling; the deposit is 2 feet in depth. In *Wimpole street*, for about 150 feet of this sewer, the bottom is washed away, and the side walls undermined.

Upper Brook-street.—Sewer in a crumbling state.

In *Curzon street.*—The springing walls are crushed in on both sides, at various places, for the distance of 150 feet; the rubbish lying about the sewer obstructing the discharge, and the deposit accumulating so fast that the sewer will shortly be choked up altogether.

Parliament-street.—The side walls for 200 feet, joining Bridge-street, are in a ruinous and crumbling condition. The north end is filled with deposit to the soffit, although the sewer is 5 feet 10 inches by 3 feet 2 inches. The smell is horrible. *Whitehall and Spring-gardens* contain from 3 feet to 4 feet of detritus deposit; and in *Hanover and Berkeley-squares* a considerable deposit exists, emitting most offensive effluvia. *Fitzroy-square.*—The invert of this sewer nearly all washed away.

We might continue our abstract from this Report, surveying the whole line of princely buildings of Belgravia on the one side, and Hyde Park Gardens on the other, *finding* only *one little* spot in Westminster district—namely, Seven Dials, in a satisfactory state!

Cholera in Dumfries.—In reference to letters we have lately published, from Drs. Grieve and Barker, of Dumfries, we think it right to transcribe from the *Monthly Journal* the following extract from a report by Dr. Barker, on cholera in Dumfries:—"My time of acting-physician at the Infirmary being from the 1st of September till the 1st of January, all the cases were under my charge except six, who were admitted subsequently to the latter date. I therefore feel called upon to correct the statements made in your *Journal* of this month, (May,) regarding the cholera in Dumfries. The greatest care was taken to keep the cholera patients separate from the others. As there was only one case of fever in the house, the four fever wards were set apart for the reception of cholera cases, and these wards occupy the whole of the upper story of the house: the solitary fever patient remained in one of them, but that could not be helped. When these upper wards were full, a large ward in the extreme wing was used; but all the other patients were removed from it to other wards, or dismissed. One of the surgical patients acted as night nurse for the cholera wards, for twelve or fourteen nights, when we had difficulty in procuring nurses. Another man presented himself in the waiting-room as an out-patient, but was not ailing much; when, as he was not afraid of the disease, I engaged him to come into the house as a nurse, which he did for payment, and acted as such so long as we had cholera patients. We had thus, during its continuance, five nurses for the cholera wards solely, one of whom died almost at the commencement of the epidemic of cholera, after twenty-three hours' illness, which she could scarcely have caught, as reported, by going up into the town, as there were, at that time, almost no cases of cholera in the town except in St. Michael's-street, and its immediate vicinity, at the southern end of which the Infirmary stands. At the time of her seizure, this was the principal nurse for the upper wards, and was, of course, the one who had most to do with the cholera cases. Of the officers of the Infirmary, Mr. M'Lauchlan, the acting surgeon, died on the 10th of December, as was reported to the Board of Health. As his time for attending the Infirmary was the same as mine, and as we met there every day, I asked him to go up the wards with me whenever he could spare as much time, which he frequently did, as he was much interested in the history of the disease; and he went round the wards with me within a week of his death. Thus we had one death out of nine resident medical men; none of the others had cholera I believe, but more than the half of them were confined to the house for some days at least, with the premonitory diarrhœa. Out of twelve medical men who were brought to Dumfries during the visitation, two were attacked very severely, of whom one died. Whilst I am perfectly sure that cholera spread in Dumfries as an epidemic, I am by no means sure that it did not spread also by contagion, more particularly when a number of cases were congregated together, without a due amount of proper ventilation. It may not be out of place to mention here, the appearance of cholera at Clarencefield, although I cannot, at the moment, find a paper to give me the correct dates. Clarencefield is a small village in the parish of Ruthwell, nine-and-a-half miles south-east from Dumfries, between which places a postman went regularly every second day. Having been in Dumfries in the beginning of December this postman was seized with cholera after reaching home, and died. The medical man of the parish, who attended him, and who had not been near Dumfries, was next seized and died. A female, who waited upon one or both of them, was also seized, but recovered. And an elderly lady, who had been near none of these three, was also seized with cholera, and recovered; however, a relative of hers, a medical gentleman returned from India, was living in the house with her, and he had been frequently visiting both the postman and the medical man during their illness, though he was not attacked himself. These facts are strong; they are well known to all the medical men here; and are apt to stagger the opinions of those who hold that the disease is not contagious, especially as in this instance there were no other cases, so that it would be difficult to consider the above an epidemic visitation."

The Late Mr. William Clift, F.R.S.—We have just seen an admirable likeness of this noblest work of God, an honest man." It will be recollected that Mr. Clift expired a few weeks since, when we gave a short biographical sketch of the deceased. Mr. Bosley, the artist, has lost no time in producing a very faithful and characteristic likeness of our lamented friend. Every member of the College ought to possess a copy of this portrait (taken from a Daguerreotype) of a man who served them so long and so faithfully as did Mr. Clift, the Conservator of the Hunterian Museum.

Clot-Bey, the celebrated Egyptian surgeon, has returned to France. Writing from Cairo to the Editor of the *Union Médicale*, he desires to inform his professional brethren, that he retires from his laborious post with the most flattering testimonials from the Viceroy, addressed *"au très honorable, très habile, très distingué Clot-Bey, notre ami fidèle."* He served twenty-five years in Egypt, and retires with a pension of 16,000 francs a year, (about 640*l.*,) with the half to his children, if he dies before they attain their majority.

A Speaking Mummy!—A Waterford physician, who tacks to his name A.M., M.B., T.C.D., has written to the *Mail*, published in that city, in reference to a mummy found in the guano at Ichaboe, some time since, and now exhibiting in Waterford. He concludes his letter by declaring, that the mummy *"speaks* for itself."

MORTALITY TABLE,
(Metropolis,)

For the Week ending Saturday, July 14, 1849.

Causes of Death.	Total.	Average of Five Summers.
All Causes	1369	1093
Specified Causes	1367	1005
Zymotic (or Epidemic, Endemic, and Contagious) Diseases	630	302
Sporadic Diseases:		
Dropsy, Cancer and other Diseases of uncertain or variable seat	42	44
Tubercular Diseases	204	190
Diseases of the brain, Spinal Marrow, Nerves, and Senses	106	119
Diseases of the Heart and Blood-vessels	28	29
Diseases of the Lungs, and of the other Organs of Respiration	108	81
Diseases of the Stomach, Liver, and other Organs of Digestion	60	76
Diseases of the Kidneys, &c.	10	11
Childbirth, Diseases of the Uterus, &c.	10	7
Rheumatism, Diseases of the Bones, Joints, &c.	7	7
Diseases of the Skin, Cellular Tissue, &c.	3	2
Malformations	3	3
Premature Birth and Debility	21	22
Atrophy	33	27
Age	36	41
Sudden	13	8
Violence, Privation, Cold, and Intemperance	53	36
Causes not Specified	2	3

The following is the number of Deaths occurring from some of the more important special causes:—

Apoplexy	21	Heart	28	Phthisis	116
Bronchitis ...	28	Hooping cough	37	Pneumonia ...	52
Cholera.........	339	Hydrocephalus	25	Scarlatina	25
Childbirth	4	Influenza		Small pox	0
Convulsions...	30	Liver	12	Stomach	2
Diarrhœa	89	Lungs	6	Teething	13
Dropsy	17	Measles	30	Typhus	49
Erysipelas ...	11	Paralysis	17	Uterus	4

BIRTHS AND DEATHS.

	Births.	Deaths.	Deaths over Births.
Males	634	702	68
Females	592	667	75
Total......	1226	1369	143

TO CORRESPONDENTS.

A Correspondent who signs himself "Philanthropist," asks us various questions in reference to an institution said to be established in London some years ago, and called the "Sanatorium." All that we can say in reference to it is, that it was introduced for persons whose station in life placed them above the reach of charity. We are not aware that the "Sanatorium" is at present in existence.

"Jabez."—The disease is universally acknowledged to be infectious, and the infecting distance is undoubtedly considerable, although not determined by observation. It is communicable by fomites of every description.

"J.B."—Fungi have been discovered in the scalp in the disease referred to.

"Amicus."—We are unable to give our correspondent the information he seeks "on luminous animals." We only know that those which are so singularly endowed occupy the lower position in the zoological scale.

"Medicus."—The excellent work of Dr. Mason Good should be consulted.

"Questor."—(1) It is impossible to say what cases of idiotcy are incurable. The trial must be made. Neither the smallness of the head nor the hydrocephalic enlargement are signs on which any opinion as to the result can be formed. The most unpromising cases, we believe, are those attended with hemiplegia, chorea, and epilepsy. (2) An Asylum for Idiots has been established in the neighbourhood of London.

"B.M., Glasgow."—We have found the nitrate of silver a very useful remedy in stomatitis—about one-eighth of a grain at a dose, dissolved in a drachm or two of distilled water.

"An old Subscriber" says, that he has recently attended a female patient, six months advanced in pregnancy, in whom there appeared large dark coloured patches on the surface of the body. The lady, he says, is about twenty-five years of age, and of fair complexion. Our correspondent wishes to know if this phenomenon has been mentioned by medical writers. Yes.

"Meteorologist."—Our own observations do not enable us to offer an opinion, but a celebrated German writer says, that the influence of weather and season upon health varies with the different periods of life.

"Juvenis, Manchester."—(1.) The examination for the degree of Doctor of Medicine in the University of London takes place only once a-year, commencing on the fourth Monday in November. (2) Fee, £10

"T C D," adverting to our Editorial Article on smoke, in last week's Number, wishes us to forward to him a list of patents granted for the consumption of smoke. Our Correspondent had better apply at the Office for Patents.

"Provincial"—The students of the Queen's College, Birmingham, are admitted to examination for the scholarships, exhibitions, gold medals, &c., offered by the Senate of the University of London.

"F R.S."—Not at present.

"Mr Cripps."—It is uncertain.

"*,*"—The communication must be authenticated before it can be published.

"An Army Surgeon."—A private communication shall be forwarded.

"M.R C S, Birmingham."—We have had the article sent analyzed by a skilful chemist, who pronounces it highly adulterated.

"Dubitans"—The test, according to the law of England, is the presence or absence, at the time of committing the criminal act, in one of diseased mind, of the consciousness of right and wrong. We agree with our Correspondent on the incompetency of juries, as at present chosen, to decide in matters relating to criminal insanity.

"Obstetrician."—Yes, the discharges referred to are not unfrequently witnessed in young females before the age of puberty, and they are by no means uncommon in those who have ceased to menstruate.

"Sine Spe."—The fears are groundless, the Profession will have an opportunity, during the recess, of examining closely any measure of medical reform which may be introduced into Parliament.

"A Legal Practitioner" should either be content with his present qualification, or seek some more honourable way of obtaining the degree of M.D.; by mere purchase, such diplomas are valueless.

"Nemo."—The medical men who sign the certificates in cases of lunacy, must state the facts upon which their opinion is grounded.

"A Medical Supporter."—We have not time to undertake the inquiry suggested.

"Æsculapius."—A candidate with the double qualification will be preferred.

"Electrician."—The ancients knew nothing of electricity as a science; their knowledge being confined to the fact, that amber and lincurium, supposed to be tormalin, attracted light bodies by friction. It was not known that other bodies may be similarly excited until the commencement of the 17th century, when Gilbert, of Colchester, detected the same property in a variety of other substances, and thereby laid the foundation of the science.

"A Constant Reader, Norwich."—On an average, human blood contains 60 or 70 parts of albumen in 1000; in some few cases it has been known to increase above 80.

"Zeta" complains that the registrar of his parish receives certificates of the cause of the death from druggists. He says that some cases have come to his knowledge which have been attended by illegal practitioners, and, the patients dying, the Registrar has taken no trouble to ascertain if the certificates have been properly given. Our Correspondent should lay the matter before the Registrar-General, who will take measures to remedy the evil.

"A Provincial Subscriber."—Belladonna will not cause a dilatation of the pupil under the circumstances mentioned.

"M.R.C.S." can obtain the articles mentioned at any medical fixture dealer's; we would recommend him to obtain the wire gauze blinds at Fox's, on Snow-hill. Our advertising columns will frequently give him the information he asks.

"A Navy Surgeon" shall have his request attended to. We are not without hope that the grievances under which the Assistant-Surgeons labour will, ere long, be remedied. Even the Lords of the Admiralty are not insensible to public rebuke, though they may wish to appear regardless of it. Increasing difficulties to supply the navy with educated medical officers will force from "My Lords," eventually, if nothing else will, that measure of justice which they appear so reluctant to grant.

"Iota."—The Apothecaries' Company has no power over persons practising purely as physicians.

"Justus" should address a letter to the Secretary of the College of Physicians.

"———."—Hyoscyamine and its salts are more uniform in their action than the plant, extract, or tincture.

"Mr. Carpenter, of Castlecomur," has forwarded us a case of malignant cholera, which occurred in a strong man, who had been suffering from diarrhœa for three months. When first visited he was affected with violent spasm, voice hoarse, heart's action neither to be felt nor heard, skin cold, thirst incessant. Hot spirit of turpentine directed to be laid over the heart and spine, and a blister over the xiphoid cartilage, hot water to the loins and soles of the feet. Half a-dram of Liq Kali pur. with 15 minims of Tinct. Opii, in two ounces of water, to be given immediately. After three doses of this medicine, without any perceptible change, a pint of fluid was evacuated from the bowels, in appearance like badly-prepared whey. The pulse then became perceptible at the wrist Another dose of the medicine was given in half an hour afterwards, and the following mixture:—℞ Bicarb. Sodæ, ℈ij.; Mist. Camph., ℥iv., Tinct. Opii, ℨi.; Sp. Æth. Nit. ℨiss. M., an ounce to be taken every hour, commencing an hour from the last dose of the other medicine. In the evening the cramps became less frequent, perspiration supervened, and the bowels became quiet. By midnight the heart's action was restored, after a comfortable sleep. Two grains of calomel were ordered next evening, and afterwards an effervescing mixture every two hours. From this time the patient began rapidly to improve, and in two days he was pronounced quite well.

"Chirurgus." — (1) Dr. Stevens is about to publish his method of treating cholera (2) To prepare Hæmatosine, blood is well stirred to separate the fibrine, and mixed with six volumes of a saturated solution of sulphate of soda, in which the globules are insoluble They are then boiled with alcohol acidulated with sulphuric acid, which dissolves a sulphate of hæmatosine, and leaves a sulphate of globuline. The red alcoholic solution is mixed with carbonate of ammonia, which separates the sulphuric acid and sulphate of ammonia along with a little globuline. The filtered solution being evaporated, leaves hæmatosine as a dark brownish red mass.

"Mr F. E. Lander, Shiffnall."—We are not aware of a second volume having been published.

"A Surgeon, Bristol."—A medical certificate-book of the cause of death may be obtained gratis, on application to the registrar of the district.

"Humanitas" had better address a letter to Dr. Stevens, Worcester.

"Audax."—(1) We know not how the degree of M.D. can be obtained without our correspondent leaving his practice for a short time. The degree is not now to be procured at any of the German universities by mere purchase. We rejoice in this alteration. (2) The expense varies in different universities. Our Students' Number may be consulted with advantage.

"Cod Liver Oil."—A Correspondent wishes to know the most agreeable way of taking Cod Liver Oil. We fear bad is the best, and that rendered worse since the value of the medicine has been much over-rated. We know a patient who takes it in orange-juice; lemon-juice, wine, and brandy, have been recommended. Madeira is said to conceal its very nauseous taste. Bennett and Macfarlane give it in peppermint, aniseed, or cinnamon. The former, however, causes eructation, and the unhappy patient, though he swallows one dose, tastes many. Duclou advises it to be administered in the form of an emulsion, with gum arabic, simple syrup, and orange-flower-water. All authorities, however, seem to agree, that it is most efficacious when taken pure.

"M.R.C.S London and a Disinterested Party," will see the subject discussed in this day's Journal.

"Mr. J. D. Milner, North Dispensary, Liverpool."—We cannot state positively.

"A Subscriber and Admirer."—We are obliged for the offer which we accept.

ORIGINAL LECTURES.

LECTURES ON THE PROCESSES OF REPAIR AND REPRODUCTION AFTER INJURIES.

DELIVERED AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND

By JAMES PAGET, F.R.C.S.

Professor of Anatomy and Surgery to the College

[Reported for the "Medical Times."]

LECTURE IV.

Development of blood vessels in granulations; their modes of formation in the embryo; their formation in granulations and similar new productions by outgrowths and channelling—Healing by secondary adhesion or union of granulations—Healing by scabbing; its several modes and advantages—Process of suppuration; Relation of the pus cells to granulation cells and inflammatory exudation cells, and of the *liquor puris* to fibrinous blastema—Probable degeneration of other cells into pus cells—Characters of scars; their contraction and gradual perfection.

MR. PRESIDENT AND GENTLEMEN,—There was an omission in the last lecture respecting the development of the substance lying between the granulation cells. This is not to be seen except in granulations which are well formed; and in them there lies a solid substance, in which there cannot be discerned a definite structure, but which passes through the several structures, and forms fibrinous cellular tissue. Their nuclei, after the addition of acetic acid are found embedded in a fine pellucid gauze-like substance. In the more degenerate kinds, perhaps, none of this substance is found; but in all the perfect kinds it exists, and takes part in forming the cellular tissue. Together with the process of development of the mere structure, there is a chemical character which is the contrary of development; for, as it loses the albuminous character, so it recedes from the character of highly organised chemical compounds. As the granulation cells become more and more formed, it assumes the character of fibrine, and then all its albuminous character is lost, and fibrinous cellular tissue is formed. In the development of granulations, in structure they coincide with the general rule, that all animal structures in the process of development are of the highest chemical composition, while all those, with very little change of particles, are of a comparatively low composition. In the blood albumen and fibrine abound, but no gelatine; but, in the cells which hold the blood, they approximate closely to the lower vegetable and inorganic compounds. In their first production they are formed of highly albuminous principles, and then degenerate into gelatine; but, like the common development of cellular tissue, they gain according to the length of time for which they must exist. I have hitherto spoken of the structure and elements of granulations, but coincidently with this there ensues a production of blood vessels for the further development of its structure, and it is a question of interest how these vessels are formed. Hunter's opinion was, that both the blood and vessels form in the granulation substance, as they do in the germinal area of the chick, and that, subsequently, they enter into communications with the vessels and blood of the part from which the granulations spring. But it certainly is not so, although the development of vessels is according to a method equally natural with that described by Mr. Hunter. In embryos, we may discern three several modes according to which blood-vessels are formed. In the first and earliest method, they are constructed around the blood corpuscles, which, being gradually developed from some of the embryo cells, are laid out in the plan of the earliest and simplest circulation of the blood. Thus, in the larvæ of Batrachia, as in the common tadpole, before even the walls of a heart are formed, one sees a crowd of embryo blood corpuscles collected where the heart is to be; and, in the substance of the out-growing external branchiæ, are looping lines of blood-corpuscles, around which as yet no walls can be discerned. It is so, also, with the blood and vessels of the warm blooded vertebrata; the corpuscles are rapidly developed from some of the cells of the germinal area, and are laid out in the plan of the heart, and the terminal sinus, and their communicating channels. But at first it is only as a plan; the blood does not move, and is not walled in. Then, as the heart and vessels are formed around the blood, its circulation in these simple channels is established. In this case the vessels appear to be formed of the plasma or fluid material which lies between the cells, and gradually assumes the condition of a membrane, and is then developed into the more complex structures of the blood vessels. After this earliest period of embryo life, it is probable that blood is never formed except within the vessels already constructed. It would seem as if none but the original embryo or germ-cells could be directly transformed into blood-corpuscles; all those that are later made derive their materials through a process of gradual elaboration in lymph or blood vessels, to which process no resemblance can be discerned in the substance of granulations. To increase the extent and number of vessels that must be added in adaptation to the enlargement and increasing complexity of the embryo, two methods are observed, of which the one appears chiefly appropriate to the interstitial formation of new vessels; the other, for the construction of those of superadded or outgrowing parts. For the former, one finds, in the interspaces of vessels already existing, primary cells which enlarge and elongate, and send out branches in two or more directions,—branches sometimes so exceedingly slender, that one might take them for mere threads of embryonic fibro-cellular tissue. But they are hollow; and while some of them are directed into anastomosis with each other, others extend towards, and open with dilatations into the vessels already formed and carrying blood. Then, these fine branches of each stellate cell becoming larger, while the main cavity of the cell from which they issued, attenuates itself, they are altogether transformed into a network of nearly uniform calibre, and through these the blood, entering by the openings of communication with the older vessels, makes its way. Thus the wide spaces of the network formed in the primordial circulation are subdivided into smaller meshes, and each part receives a more abundant supply of blood. Such a development (as shown in diagrams) may be seen in the soft gelatinous matter within the amnion of embryo sheep, and in the tissue of the tail of the tadpole; though in this last the development is often abortive, in consequence of the tail being so often a temporary organ. But, for parts that are formed by superaddition or outgrowth, another mode of development of blood vessels is observed, and this, I believe, is the only mode in which new blood vessels are ever formed for granulations or for superficial deposits of lymph, adhesions, and the like,—a process indicated in the specimens illustrating the repair of similar wounds which were purchased by the College from the Museum of the late Dr. Poll, of Brighton; and there is no reason to suppose that any other method prevails for the supply of blood vessels to any granulations, or similar new productions. For, though the process in granulations or in lymph cannot be exactly watched during life, yet every appearance after death is consistent with the belief that it is the same as I have described, and no appearances are found which would justify a suspicion that either of the other methods of development has occurred.

Suppose a single arch of capillary vessel passing below the edge or surface of a part to which new material has been superadded. The vessel will first present a slight dilatation in one, and coincidently, or shortly after, in another point, as if its wall yielded a little near the edge or surface. The slight pouches thus formed gradually extend, as blind canals or diverticula, from the original vessel, still directing their course towards the edge or surface of the new material, and crowded with blood corpuscles, which are pushed into them from the main stream. Still extending, they converge; they meet; the partition-wall, that is at first formed by the meeting of their closed ends, clears away, and a perfect arched tube is formed through which the blood, diverging from the main or former stream, and then rejoining it, may be continuously propelled.

In this way, then, are the simplest blood-vessels of granulations and such out-growths formed. The plan on which they are arranged is made more complex by the similar out-growths of branches from adjacent arches, and their mutual anastomoses; but, to all appearance, the whole process is one of out-growth and development from vessels already formed. And I beg of you to consider the wonder of such a process; how, in a day, a hundred or more of such loops of fine membranous tube—less than 1-1000th of an inch in diameter—should be upraised, not by any mere force of pressure, though with all the regularity of the simplest mechanism, but each by a living growth and development, as orderly and exact as that which we might trace in the part most essential to the continuance of the life. Observe, that no force so simple as even that of growth or mere assimilation can determine such a result as this; for, to achieve the construction of such an arch it must spring with due adjustment from two determined points, and then its flanks must be commensurately raised, and these, as with mutual attraction, where the millionth part of digression would spoil the whole, must approach and meet exactly in the crown. Nothing could accomplish such a result but a power determining the concurrent development of the two out growing vessels, in conformity with the same law as that according to which the same power actuates the germ. We admire the intellect of the engineer, who, after years of laborious thought, with all the appliances of weight and measure, and appropriate material, can begin at points wide apart, and force through the solid masses of the earth one tunnel, and can wall it in secure from external violence, and strong to bear some ponderous traffic,—and yet he does but grossly and imperfectly imitate the Divine work of living mechanism that is hourly accomplished in the bodies of the least conspicuous objects of creation—nay, even in the healing of our casual wounds and sores.

This process is sometimes interrupted, as shown in a series of experiments by Mr. Quekett. It sometimes happens that the little pouches which spring up will burst, and then a number of corpuscles are infused into the surrounding parenchyma of the tissue. The blood corpuscles that issue from the ruptured pouch or diverticulum collect in an uncertain mass within the tissue, like a mere ecchymosis; but before long, they manifest a definite direction, and the cluster bends towards the line in which the new vessel might have formed, and thus opens into the other portion of the arch, or into some adjacent vessel. For this mode of formation from vessels, the name of *channelling* seems more appropriate than that of out growth; for it appears certain that the blood corpuscles here make their way in the parenchyma of the tissue, unconfined by membranous walls. The occurrence of such a process of channelling as is here indicated loses all improbability, when we remember that in insects the blood habitually flows, in a considerable and important part of its course, simply filtering through the parenchyma, and running in the interspaces between the cellular tissue. In such channels, too, it seems very probable that the blood moves in part of its course through some of the softer medullary and other morbid growths; at least, in these I have often found it impossible with the microscope, to detect even the rudiments of such vessels as could carry their great supplies of blood. The general characteristics presented by the blood-vessels in granulations are shown in some preparations by Sir A. Cooper, which display that the vessels which pass into the substance of granulations run vertically towards their surface, springing up gradually, and rarely branching. Of these branches, some probably represent the loops or arches successively formed in the deepening layer of granulation cells, while others must be formed by offshoots from the sides and other parts of the several arches.

Near the surface of the granulations, at a very little distance below the outermost layer of the cells, the vessels communicate much more frequently, and form their loops or terminal arches, which generally lie between the tubercles which crown the summit of granulations. On the same plan are formed the vessels of the walls of abscesses lined with granulations; so, also, Sir A. Cooper described them in granulations from an ulcerated scirrhous cancer; and I have found the same general plan in the warty ulceration of soot-cancer on the scrotum.

The structure of the new vessels formed in granulations also agrees with the described mode of development. In the earliest period of their appearance they present no indication of being formed by the fusion, or any transformation of the granulation cells, but consist of thin membrane, in which, if it be not quite simple, nuclei or cytoblasts are imbedded. These nuclei pass through the same stages of development, by narrowing and elongation, as those I have described in the nucleated blastema; and thus they become like the pieces of flat fibre that one sees on the walls of the original vessels of the same size. Like them, also, they are arranged, some longitudinally, and some transversely to the axis of the vessels giving them a most peculiar appearance.

Respecting the purpose of the supply of blood thus sent to granulations, one traces, in the development of vessels, a series of facts exactly answering to those in ordinary embryonic development. Organization makes some progress before ever blood comes to the very substance of the growing part; for the form of cells may be assumed before the granulations become vascular. But, for their continuous active growth and development, fresh material from blood, and that brought close to them, is essential. For these the bloodvessels are formed; and their size and number appear always proportioned to the volume and rapidity of life of the granulations. No instance would show the relation of blood to an actively growing or developing part better than it is shown in one of the vascular loops of a granulation, imbedded among the crowd of living cells, and maintaining their continual mutations. Nor is it in any case plainer than in granulations, that the supply of blood in a part is proportionate to the activity of its changes, and not to its mere structural development: the vascular loops lie imbedded in the simplest primary cells, or, when granulations degenerate, in structures of yet lower organisation; and, as the structures are developed, and fibro-cellular tissue formed, so the blood-vessels become less numerous, till the whole of the new material assumes the paleness and low vascularity of a common scar.

Of the development of nerves and other structures in granulations, I have been quite unable to see any in either granulations or cicatrices. The acute sensibility of granulations would indicate the presence of nerves; but it would be more satisfactory to see them; for the force of contact may stimulate the nerves beneath them.

As to lymphatics in granulations, I believe they do not exist. Professor Schroeder van der Kolk tells me that they cannot be demonstrated in the skin, even in the healthy state, except in the scrotum, so that the active absorption must be accompanied by the agency of blood-vessels. It is manifest that the development of granulations and all their structures is accomplished according to a plan which is a mere repetition of that engaged in the embryonic tissues; and perhaps there is no better distinction between these than in the different degrees in which they are subject to disease. Amongst the embryonic tissues there is scarcely any deviation from the elementary structure; but among the tissues formed for the repair of injury, deviations are amongst the most common phenomena. A very few observations on the structure of granulations will prove the existence in them of diseases; one can trace the arrest of development of granulation structures; years may pass, and there may be no change; they do not pass on to development so as to heal. Again, they may degenerate, so that in fact, the walls are formed of corpuscles which resemble pus; or in dying persons they degenerate into a mere mass of debris. And so we may trace congestions; or, again, they inflame and suppurate so as to extend through the mass of granulations.

Perhaps I should now speak of the process of suppuration, but I will first briefly refer to the two remaining modes of healing open wounds. 1. By secondary adhesion. 2. By scabbing. The surfaces of granulations, if not covered with cuticle, and if placed in contact, will completely unite, and then the next succession of blood-vessels, instead of passing the arch will pass across between the two, and form anastomosis with the granulation cells they are in contact with.

Mr. Hunter describes this process:—"Granulations have the disposition to unite with one another when sound or healthy; the great intention of which is to produce the union of parts, somewhat similar to that by the first intention, although possibly not by the same means." And "I have seen two granulations on the head, viz., one from the dura mater, after trepanning, and the other from the scalp, unite over the bare bone which was between them so strongly in twenty-four hours, that they required some force to separate them, and when separated they bled." In illustration of the process he put up a preparation, which he described as "granulations under the skin in an abscess in the leg, which were opposed by others on the muscles, and which were to unite. Those under the skin only are saved and folded towards each other, to show the opposition of two granulating surfaces."

There are several circumstances in which the healing by secondary adhesion should be attempted, —such, for example, as I witnessed in a case which was lately in St. Bartholomew's. After an ordinary circular amputation of the thigh, no immediate union and no primary adhesion had taken place, and the whole interior of the stump was granulating. Had it been, as the expression is, left to granulate, or to fill up with granulations, the healing process would have occupied at least a month or five weeks more, and would have greatly exhausted the patient, already weakened by disease. But Mr. Stanley ordered the stump to be so bandaged that the opposite surfaces of granulations might be brought into close contact: they united, and in a week the healing of the stump was nearly perfected.

In all such cases—and I need not say that they are very frequent—the healing by secondary adhesion may be attempted without danger, and with manifest advantage.

Again: Mr. Hunter operated for hare lip, and no primary adhesion of the cut surfaces ensued. He let them both granulate: then brought the granulations together, as in the common operation, and they united, and healed soundly. And Mr. Skey told me he had operated for fissure of the soft palate. The very edges of the wounds sloughed and retracted, and the case seemed nearly hopeless; but he kept in the sutures, and granulations sprang up from the edges of the cleft, after the separation of the sloughs; they met in the mid-space of the cleft, and coalesced, and formed a perfect scar.

Doubtless, cases like these are of no rare occurrence; but I am induced to mention them as illustrations of a process of which the importance and utility are not generally considered, and which is rarely applied in practice.

The treatment of wounds by scabbing may be regarded, as Mr. Hunter says, as the most natural one, for it is the method by which one sees nearly open wounds healed in animals; for in them, even in the warm-blooded, it is difficult to excite free suppuration from the surfaces of wounds; they quickly become coated over with a scab formed of the fluids that ooze from them and entangle dust and other foreign bodies; and under such a scab the scar is securely formed.

In general, the scabbing process is effected by some substance effused on the surface of the wound, drying there, and forming a hard and nearly impermeable layer. The edges of this substance adhere over those of the wound, so as to form for it a sort of air-tight covering, under which it heals without suppuration, and with the formation of a scar, which is more nearly like the natural parts than any scars formed in wounds that remain exposed to the air, and which does not, like them, contract, so as to produce deformity of the parts about it.

The scab may be formed of either dried blood, dried lymph and serum, or dried purulent fluid. Instances of the healing of wounds under dried blood are not rare. It is especially apt to occur in the cases of wounds in which a large flat surface is exposed, as after the removal of the mammary gland. The most remarkable case of this kind is recorded by Mr. Wardrop; the largest wounded surface he ever saw, remaining after the removal of a diseased breast, almost entirely healed under a crust of blood, which remained on for more than thirty days. But the most common examples of healing under blood scabs are in small wounds—such as are made in bleeding, or, more rarely, in some compound fractures. The excellent, though nearly obsolete, practice of laying on such wounds a pad of lint soaked in the blood, was a good imitation of the most natural process of their repair.

If a blood-scab be not formed over a wound, or if such an one have been detached after being formed, then at once a scab may be derived from the serum and lymph that ooze from the surface of the wound. Thus it is commonly with wounds in animals that are left to themselves, and in many small wide-open wounds in our own case. Thus, also, I imagine, the best healing of burns and scabs is effected, when the exposed surface is covered with cotton-wool or other substance, which, as the oozing fluids become entangled with it, may help them to form a scab.

At a yet later period, the pus produced from exposed granulating wounds may concrete on them, and they will heal under it excluded from the air. Such a process may also ensue in the healing of ulcers. In any case the healing process is probably just the same as that under scabs of blood or serum; but, I believe, it has not yet been exactly determined what are the changes that ensue in the surface beneath the scab. So far as one can discern with the naked eye, the wounded surface forms only a thin layer of cuticle on itself; no granulations, no new cellular tissue, appears to be formed; the raw surface merely skins over, and it seems to do so uniformly, not by the progressive formation of cuticle from the circumference towards the centre, as is usual in open wounds.

The healing of a wound by scabbing has always been thought a desirable process; and when one sees how quickly, by means of this process, wounds in animals are healed, and with how little general disturbance, one may well wish that it could be systematically adopted. But to this there seems some hindrance. Many surgeons have felt, as Mr. Hunter did, that the scabbing process should be permitted much oftener than it is, in the cases of both wounds and ulcers; but none have been able to lay down sufficient rules for the choice of the cases in which to permit it. Probably, the reason of this is, that, at the best, in the human subject, the healing by scabbing is an uncertain process. When the scab is once formed, and the wound covered in, it is necessary that no morbid exudation should take place. Whenever, therefore, inflammation ensues in a wound or sore covered with a scab, (and this, I need hardly say, is a very common event) the effused fluid, collecting under the scab, produces pain, compresses the wounded surface, or forces off the scab, with great discomfort to the patient and retardation of the healing. I suspect that the many instances of disappointment from this cause have led to the general neglect of the process of scabbing in the treatment of wounds. The observance of perfect rest, and of the other means for warding off inflammation, might, however, yet make it an available auxiliary in the treatment of wounds, especially of large superficial ones; for, in the treatment of small wounds, collodion appears sufficient to accomplish all that scabbing would do.

Such are the several methods of healing observed after wounds of soft parts; and, in connexion with them, two subjects remain to be considered, namely, the process of suppuration, and that of the perfecting of scars.

LECTURES
ON
OPERATIVE OPHTHALMIC SURGERY.
DELIVERED AT THE CENTRAL LONDON OPHTHALMIC HOSPITAL.

By H. HAYNES WALTON, Esq., F.R.C.S., Surgeon to the Hospital, and to the St. Pancras Royal General Dispensary.

LECTURE II.

Lenticular cataract, its subdivision.—Consideration of the natural changes occurring in the lens, in elucidation of the nature of cataract.—Hard lenticular cataract, its appearances, peculiarities, and varieties.—Soft lenticular, ditto, ditto.—Capsular cataract, classification of.—Congenital cataract.—Morgagnian cataract.

GENTLEMEN,—*Lenticular Cataract* may be divided into two genera, hard and soft. I shall speak of the former first; but, before entering on a description of it, I think that I shall render the subject of lenticular cataract more clear and intelligible, by a cursory sketch of the changes that the crystalline lens naturally undergoes at different periods of life.

In infancy it is nearly spherical, and softer than at any subsequent period. Its consistence increases with maturing age, its form also undergoing change; and, in the adult, is a double convex body, less prominent before than behind. About the thirtieth year, sooner or later, it ceases to be colourless, its nucleus then being of a light yellow tint; after that the colour becomes more and more marked, and pervades the entire lens, which, at a very advanced age, resembles a piece of amber, while the posterior surface gets as flat as the anterior. With this diminution of bulk and acquired colour, it is harder, or tougher, and its specific gravity is greater. You must have remarked, when looking at the eye of an elderly person, that the pupil is devoid of that blackness that is observed in youth,—there being, instead, a yellowish tint, which seems to penetrate deeply,—it is owing to the colour the lens has acquired. The yellowness is less apparent while the lens is in the eye, than after its extraction. This is just the case in cataract, which always appears darker after it has been removed.

Hard lenticular cataract, then, is merely greyness, or opacity, appearing in an already discoloured and somewhat hardened lens. It is not the property of cataract to produce hardness. A lens does not increase in density from having lost its transparency. When I tell you it is from the middle period of life upwards that hard cataract is to be seen, you will understand why.

As the opacity of a cataract is rarely sufficient to destroy the discernment of large bodies, and never the perception of light, you would naturally expect that the amber-colour would not be concealed, but more or less apparent, in proportion to the greater or less degree of opacity. So it is, and hence the characteristic appearance of hard cataract is a mixture of dark grey and amber, deeper shaded in the centre; occasionally there is a mottling of grey and amber. It must, too, be remembered, that the greater the discolouration of a lens, the less will be the amount of opacity required to obstruct vision.

Hard cataracts are spoken of as being smaller than a healthy lens. I have shown that they must necessarily be always smaller than the lens of the same individual was in early manhood.

In health, the exterior of the lens is soft, the next layer firmer, and within is the nucleus, or hardest portion. In the cataractous state the same difference is observed. There is, however, this peculiarity, that the softer part much more readily separates from the harder.

Whenever a small cataract is extracted, it is nearly uniformly hard throughout, and is, in fact, little more than the nucleus of the lens—the outer, or softer portion, having been absorbed, or left behind in the eye. You will meet with hard cataracts in the aged, that do not, while they are in the eye, seem to possess any amber colour, being whitish, or whitish grey; and, were such to be seen in the young subject, would be considered soft. I do not know that I can point out any distinction between these and soft cataracts, except that the former are uniformly white and devoid of cloudiness, and their capsules are scarcely opaque. After extraction, however, they prove to be hard amber-coloured nuclei, surrounded by a layer of soft whitish matter, apparently softer, and certainly with less cohesion than the soft superficies of a healthy lens. There is another state in which white matter is seen in conjunction with a hard amber grey cataract. I shall give you Dr. Mackenzie's description of it. He says: "In the middle-aged subject, the external half of the cataractous lens is not unfrequently whitish, and so soft that it readily mixes with the aqueous humour, when acted on by the needle, while the central half is hard and amber-coloured." I have some beautiful specimens illustrating this and the other condition; but all of them I have extracted from old persons.

I shall not stop to offer an explanation of these exceptions,—it is enough that I apprise you of their existence. Hard cataracts may be so dark as to resemble the colour of mahogany, and observers say that they have been seen of so deep a hue, that without close inspection they would have passed unobserved.

I have seen a lens quite black; it escaped from an eye when a large staphylomatous mass was removed. The organ had been destroyed some years before, by some scalding liquid. The hardness of a cataract is generally in proportion to its darkness,—hence the mahogany-coloured are the most dense. The mother-of-pearl appearance of the surface of hard cataract is not proper to it, but is seen also in the soft kind, and may, moreover, occur in capsular cataract, so that, as a diagnostic it is of no importance.

I have spoken of the most usual characteristics of hard cataract, and said enough to enable you to recognise it. It would be a waste of time to dwell on peculiarities that individual cases present. I ought to mention, that occasionally are seen streaks or radii, glistening, or more opaque than the rest of the cataract. They are not peculiar to the hard genus. Some other points remain to be noticed which I think had better be deferred till after I have treated of the other division, as they will probably be the better remembered.

Soft Lenticular Cataract.—This appellation is used when opacity invades a lens that has not undergone the amber change; or, if it should have commenced, has not proceeded to any extent; hence soft cataract, with few exceptions, is an affection of early life.

If it were any property of opacity to produce hardness, why should not hard cataract occur in early years? Again: not only does an opaque lens often become softer than natural, but may even degenerate into a fluid form.

Except in one form of congenital cataract, of which I shall presently speak, there is not, originally, any decrease in bulk, but frequently an enlargement. Now, whether that precede the opacity, or *vice versâ*, I am not able to say; neither am I aware of the nature of the enlargement.

Light grey occupies, in soft cataract, the place that the amber grey takes in the hard variety; and in proportion to the softness does the grey become lighter and lighter, assuming a milky whiteness. The discoloration is generally uniform throughout the pupil, and not darker in the centre, as in hard cataract. It may present various appearances, such as being cloudy, or like the fractured surface of a piece of spermaceti. The streaks or radii that I described as seen in the hard cataract, are observed also in the soft, with this difference, that in the latter the glistening form is more commonly seen, while, in the former, the dull predominates. These appearances may occupy the margin, the centre, or the entire surface.

Although I have had many cases of softer lenses approaching to fluidity, I do not find recorded among my notes, nor do I remember to have seen, a decidedly fluid cataract with a transparent capsule. I imagine that it is very rare. It is stated that, when fluid, two strata may be seen, denoting a heavier condition of one of them.

The size of the posterior chamber gives a sure indication of the size of a cataract; the larger the space between the posterior surface of the iris and the opaque body, the smaller will it be, and *vice versâ*. Hence, in hard cataract, which is not larger than a transparent lens, at the same period of life there is always a posterior chamber of good size—it may be very large.

In soft cataract, which, as I have said, is often larger than a natural lens, and the larger it is the softer will it be, there may be not only no posterior chamber, but the capacity of the anterior lessened, the iris being pressed against and thrust forwards, whereby its movements become impaired; indeed, the cataract may actually protrude through the pupil.

Some years since I operated on the largest cataract of this sort that I have ever seen. There was very little anterior chamber, the iris being nearly in contact with the cornea.

We cannot depend on age alone as the criterion of a particular kind of cataract, when we know how variable are the periods of life at which changes, although inevitable, shall actually occur. Authors tell us, that rarely under 45 is hard cataract seen. This is, perhaps, true, if we require as proof a well-marked amber grey colour; but cases are presented to the surgeon under that age, which are neither hard nor soft, and require the critical question, What operation shall I here adopt?

I wish to impress on you the fact, that it is not possible, on all occasions, to determine with certainty the consistence of cataract. I will relate an anecdote in point.

An acquaintance of mine, a clergyman, about 40 years old, consulted the late Mr. Tyrrell for a well-formed cataract in one eye, commencing cataract in the other. Mr. Tyrrell determined to perform the operation of extraction. His death, however, prevented its execution. I should tell you that Mr. Tyrrell never used the knife when he could employ the needle for solution. The clergyman then applied to an equally eminent, and older oculist, whose success in extraction has probably never been surpassed; and we may fairly suppose he thought the cataract not sufficiently hard to demand extraction, for he operated by solution. Here, then, we have eminent men in extensive practice differing on the question of consistence, and deciding on different operations. Unfortunately, the eye was lost, in consequence of inflammation ensuing on the second use of the needle.

You must not be surprised to hear, that soft cataract may occur in the aged. I cannot imagine, in such instances, that the lens has not observed the natural law, and remained of the same consistence as in youth; but, rather, in consequence of some pathological change after having been once hard, it has become soft. This idea is borne out by the change that may occur in soft cataract.

A very marked difference of consistence sometimes occurs in the eyes of the same individual. I will mention an instance. I operated last year on a female at 69, and removed a cataract with a hard, amber-coloured nucleus, surrounded by very soft white matter. The capsule unbroken escaped with the lens. The operation succeeded. As the patient desired to have the use of both eyes, on the 10th February I operated on the second. The appearance of this cataract was totally different; it was greyish white, and, unlike that of the other eye, pressed against the iris, obliterating the posterior chamber, and greatly diminished the capacity of the anterior. After extraction, it did not exhibit the slightest amber tint, but looked like a lens from a young person, slightly opaque in the centre, but more so on the anterior and posterior surfaces. I pointed out the peculiarity to friends present, among whom were Messrs. Gay and Shute.

There is now an out-patient attending this Hospital, aged 72, who had cataracts of two years' duration, exhibiting, in a well-marked manner, the characteristics of softness. The capsules were, in part, slightly opaque. I performed the operation for solution.

Hard cataracts are now and then so friable as to break in pieces under slight force. They seem to be preternaturally dry,—they do not lose their colour while undergoing the change. If lenticular cataract be viewed sideways, the degree of opacity appears much less than when looking directly at it.

Capsular Cataract, or opacity of the capsule, is almost invariably of a dead or chalky whiteness, rarely shining, and always showing the same opacity in whatever position we look at it. In systematic works, capsular cataract is arranged under varieties depending on its thickness, the nature of adventitious deposits on it, the position and size of partial opacities, or the amount of diminution in the contained lens. I shall not follow such a classification, preferring rather, for my purpose, the following:—Partial capsular, the lens transparent or more or less opaque—complete capsular, enclosing a lens—and capsular only.

Partial Capsular Cataract, the lens transparent or more or less opaque, occurs in one or more spots, which may vary in size and situation; such opacity may be easily recognised by its definite outline, anterior position, and whiteness; and these characteristics are rendered more manifest, by raising the upper lid, desiring the patient to direct the eye to the ground, and looking obliquely into the pupil. You can then see behind any opacity, and better understand what I describe.

Complete Capsular Cataract, enclosing a lens, is judged of by its whiteness, prominence, and extent.

Capsular Cataract only.—One cannot always say when a capsule which has not been lacerated is freed of its lens; but it may generally be concluded that capsule alone is present when, in addition to being much flattened, and far behind a retracted iris, it has shrunk at the sides, being partially or wholly separated from its ciliary connexions.

The more or less ragged and irregular capsule that remains after operations is so palpable as not to need description. Partial opacity of the capsule may be met with in conjunction with partial opacity of the lens, and the colour of the two may so resemble each other, that without looking into the pupil in the manner I have described, an inexperienced observer may be deceived. The definite outline of the capsule will be well contrasted with the posterior, hazy and diffused lenticular opacity. This scarcely involves a practical point, but I have ventured to mention it.

The posterior part of the capsule, differing in structure from the anterior, has not the same tendency to become opaque; indeed, such an occurrence alone, without the lens and anterior part being also opaque, has occasioned much controversy, and, like many other subjects in surgery that are squabbled about, is not worth the time devoted to the dispute. Its existence is said to be indicated by deep-seated radiating concave lines, with dull appearance. Really we have no means of telling whether such opacity be in the capsule or lens, and it is a matter of no practical moment; for, with the appearance that is said to indicate posterior capsular opacity, the lens sooner or later become opaque.

Mr. Tyrrell says, that he has proved in several instances the lens to be the seat of such opacity, and not the capsule.

No proof is wanting of the posterior part becoming opaque in conjunction with the anterior. On two occasions, while performing the operation for extraction, the entire capsule, quite opaque, has escaped.

The capsule is rarely so densely opaque throughout, except it be caused from injury, as to conceal the colour of the lens it incloses; some little spots, less altered than the rest, afford the information. The changes that are effected in the capsule are not influenced by the age of the individual. Precisely the same conditions may be observed at any time of life.

I have alluded to the absorbing property of opaque capsule; to what else can I attribute the partial, or entire disappearance of the lens, when the capsule has been unbroken?

Congenital Cataract.—This scarcely requires to be placed under a separate head, for in it the lens and capsule may undergo precisely the same changes that I have described as occurring in soft cataract in later years, and therefore the same rules of diagnosis are applicable. In the majority of the cases that I have seen, the capsule has been opaque and very much thickened, and contained either a small portion of lens, or merely a little milky fluid. It is said that the central lenticular opacity occasionally met with in young persons, is of congenital origin. The opacity may be of the size of a pin's head, or occupy two-thirds, or more, of the lens. Sometimes the capsule is opaque, to a corresponding extent. Purulent ophthalmia frequently leaves a similar condition, not sufficiently extensive, however, to impair vision.

There is a congenital form—that which I alluded to, called *cataracta cum zonula*—in which the lens has not grown in proportion with the other parts of the eye, and when the pupil is dilated a black zone is seen around the cataract. In all that I have witnessed the lenses were but partially opaque in infancy, and, at a later date, became wholly involved.

Morgagnian Cataract, which is spoken of in ophthalmic works, is defined to be opacity of the fluid described as existing between the lens and its capsule, both those bodies being transparent. I have nothing to say on the subject from personal knowledge. Dr. M'Kenzie thinks that he has met with one case of it; but its narration does not accord with the borrowed general description he has given of Morgagnian cataract. That a turbid fluid is found between the capsule and the lens, when they are opaque, I have had sufficient proof both while extracting cataracts and otherwise.

I am disposed to regard such fluid as the result of softening, or breaking down of the superficial portion of the cataract. I do not see any difficulty in accepting this explanation, when we know that any entire lens may become fluid. I do not believe in the existence of a liquor Morgagnii; I have never been able to detect it. This turbid fluid in the capsule may obscure the true nature of a cataract and render liable an error in diagnosis.

REMARKS ON THE OFFICE OF THE COCHLEA, AS THE SPECIAL ORGAN FOR THE MENTAL DISCRIMINATION OF THE PITCH AND AGREEMENTS OF MUSICAL SOUNDS.

By J. D. MACDONALD, Member of the Royal College of Surgeons of London.

The field of discovery which the organ of hearing opens up to the scientific mind has been occupied by the most eminent physiologists; and many theories have been raised by them in explanation of the uses to which its different structures are subservient. But notwithstanding all this, little has been established beyond the facts, that the vestibule is the most essential part of the organ of hearing, and that it allows of the perception of the intensity of sounds by the strength of the impression excited. There is no satisfactory evidence to show that its function extends either to the perception of the pitch, or the appreciation of the distance, of sounds. Hence those faculties which are not attributable to the vestibule have been assigned to its accessory parts; but at present it is only the writer's intention to endeavour to show that the perception of pitch is probably effected by the arrangements of the cochlear scala.

It is presumed that the reader is fully aware of the anatomy of the internal ear; still, it will be necessary to demonstrate the leading characters of the cochlea, as far as they appear to bear on the function in question.

The cochlea may be said to consist of about two turns and a half of a spirally coiled, tapering tube, terminating at the apex of the coil in a blind extremity, called the cupola. But there are also certain internal parts deserving more particular attention; for it is only by reviewing their structure and arrangement that just, or even probable, conclusions as to their functions can be determined. It will be well, however, for the convenience of description, to take the cochlea from its anatomical position, and suppose the cone, which its outward figure presents, to have a horizontal base and a vertical axis, and the tube which composes it to possess a superior, inferior, external, and internal wall. The central axis of the cochlea (considered a distinct structure by the earlier anatomists, and styled the modiolus) has been long since shown by the elder Monro, Ilg, and others, to be merely the internal wall of the spiral tube above mentioned, and from the coiling of which its axoidal figure results. This wall is, as it were, pinched up into a longitudinal osseous fold (spiral lamina), which floats half way into the cavity of the tube, imperfectly dividing it into two secondary canals (scalæ); but the deficiency here indicated is made up by a membraneous expansion, which is attached by one border to the free edge of the bony fold, and by the other to the outer wall of the primary tube. The two scalæ thus completely formed communicate freely at the cupola, which, as above mentioned, forms the apex of the coil. One scala lies superposed upon the other. Hence they are distinguished into superior and inferior. The former is called the scala vestibuli, because it opens by its base into that cavity; while the latter, being partitioned off from the vestibule, and opening in the dried state by the foramen rotundum into the tympanum, has been called the scala tympani. And here it is to be remarked, that the scala vestibuli composes the cupola, while the scala tympani only communicates with it by a small aperture called the helicotrema, where the upper end of the spiral lamina remains imperfect. The foramen rotundum, above alluded to, will be found in the recent state to be overlaid with a delicate membrane (*membrana fenestræ rotundæ*). There is another aperture of an oval form, the fenestra ovalis, which is also closed in by a membrane bearing its own name, and which, although not anatomically connected with the cochlea, demands a slight notice from its intimate association with the functions of that organ. This foramen, situated in the tympanic wall of the vestibule, is the common inlet of sounds passing to that cavity, and from it to the semi circular canals and scala vestibuli. The base of the stapes is attached to the membrane which closes it, and thus a direct channel is furnished by the membrana tympani externally, the membrana fenestræ ovalis internally, and the ossicles between them, for the passage of sonorous undulations, to the internal essential organ and its accessory parts. And now, without entering into the microscopical appearances of the structure of the cochlea as the teeth-like processes, observed on the bony spiral lamina and the muscular mass, said to exist on the membraneous zone, or even noticing the manner in which the vessels are supplied to the organ, we shall pass on briefly to consider the distribution of the cochlear nerve on the lamina spiralis.

The modiolus, or central axis of the cochlea, contains the fibrils of the cochlear nerve, which run, for some distance, in boney canals, and then emerge by a great number of perforations in the walls of the so-called axis, from whence they pass onwards in grooves, and terminate by forming loops, which are spread out upon the inferior surface of the spiral lamina, so that their free surface is presented in the tympanic, or inferior scala.

On surveying the anatomy of the cochlea and the mode in which the nerve loops are laid upon the spinal lamina, together with the disposition of the cochlear and vestibular fenestræ, we are led to believe that its function is very peculiar, serving, in some important way, to make perfect the faculty of audition, and the more particularly when we reflect that it is superadded to the vestibule and semicircular canal in the higher classes of animals alone. In fact, it is not only an index to the development of the organ of hearing itself, but points to the position which the being possessing it holds in the animal series. Without considering the sacculated portion of the vestibule observed in some of the lower forms of vertebrate animals, as establishing anything strikingly analogous to a cochlea, which some anatomists are led to suppose, we must acknowledge the reptilia, and indeed only among the most perfect even of them, as the crocodile, to present the first manifest cochlea which we meet in the animal creation. It consists in the crocodile of a simple canal, slightly curved, but without forming the gyri observed in the human subject. This tube

is divided by a septum into two secondary canals, which communicate at a point analogous to the cupola of the cochlea in man. They may also be respectively termed tympanic and vestibular scalæ, like those in him, and for the same reasons, so nearly is the general arrangement sketched out in both. Birds present a similar cochlea to that of the crocodile, but it appears to have advanced considerably towards the perfect condition of this part discoverable in the mammelia, where the spiral tube generally describes two turns and a-half; indeed, in some, as the porcupine, the cochlea consists of more than three coils of tube. The guinea-pig is said to possess five. In timid animals, as the hare and the rabbit, this organ is very well developed, and in dogs the spire is particularly long or prominent towards the tympanum; but all this diversity is manifestly adapted to the economy of life which the general arrangement and application of its organization enforces upon each animal. Indeed, the senses in general suffer variation in obedience to the same laws, one being extremely acute in compensation for the deficiencies of another, or all may be very complex and delicate where the locomotive powers of the animal are weak.

[To be Continued.]

BRIEF NOTICES OF THE VARIOLOUS EPIDEMIC OF 1844.

By GEORGE GREGORY, M.D., Fellow of the Royal College of Physicians, Physician of the Small pox and Vaccination Hospital.

The metropolis has seldom, if ever, been so free from small-pox as it was during the years 1842 and 1843. The deaths by that disease, recorded by the Registrar General as occurring in the metropolitan districts, (comprising a population of very nearly two millions,) were only 360 in 1842, and 438 in 1843. The admissions into the Small-pox Hospital, during those years, were 155 in 1842, 160 in 1843. The deaths in the hospital were 34 in 1842; 27 in 1843.

The first quarter of 1844 exhibited a marked increase over the last quarter of 1843. The deaths in the Registrar's Tables advanced from 114 to 252. The admissions into the Small pox Hospital increased in about the same proportion -that is, from 48 to 88. This, however, was only the breeze that foretold the storm.

The commencement of the epidemic of 1844 may be dated from the 21st of April, when the weekly mortality by small-pox in London suddenly rose from 20 to 30, and continued (with slight irregularities) progressing from that period to January 28, 1845. The quarterly deaths in the metropolis were as follows:—

1844.	1st quarter	252
	2nd „	125
	3rd „	556
	4th „	571
	Total	1,804

The highest amount attained in this epidemic was in the week ending Saturday, January 4, 1845, when 61 deaths by small-pox were registered.

The advances of the epidemic are well shown by the following Table of admissions into the Small-pox Hospital during the year 1844:—

		Quarterly.
January	26	
February	37	88
March	25	
April	31	
May	60	150
June	59	
July	64	
August	56	190
September	70	
October	68	
November	71	219
December	80	
Total in the year	647	

The admissions into the hospital in 1844 exceeded by 1 those of the celebrated epidemic of 1781; and they constitute the largest number ever admitted in one year, with the single exception of 1838, when the epidemic extended through the entire year.

Of the 647 patients admitted in 1844, 391 were males, 256 females. 538 were adults; 109 (or one-sixth of the whole) were infants or children under the age of 14.

331 were classed as "*unprotected*," but in that number were included 22 persons who alleged they had been vaccinated in early life, but whose arms exhibited *no* cognizable cicatrices. 312 had undergone vaccination, and bore upon their arms cognizable scars more or less normal. 4 had some form of eruptive fever, not variolous; viz.:— 2 *rubeola*; 1 *varicella vera*; 1 *lichen febrilis*.

Among the 312 cases of post-vaccine small-pox, 297 were adults, 15 only were under the age of puberty. The youngest of these was aged 8. Two were received aged 9; four, aged 10; two, aged 11; three, aged 12: three, aged 13.

Among the 331 persons classed as "*unprotected*," 237 were adults, and 94 (or two-sevenths of the whole) consisted of infants and children under puberty.

The mortality was as follows:—

Out of the total number admitted (647) there died 151, being 23½ per cent.

Out of the 312 admitted after vaccination, with cognizable scars, there died 24, which exceeds 7, and approaches nearly to 8 per cent.

Out of the 331, belonging to the unprotected class, there died 127, being at the rate of 39 per cent.

Of the 94 unvaccinated children, there died 43, or nearly one-half.

Of the total children admitted (109), there died 44, or 2 out of 5.

Of the 538 adults admitted, there died 107, or 1 out of 5.

The mortality among infants and children, therefore, was double that among adults. This difference is attributable to the smaller proportion of vaccinated subjects who are susceptible of small-pox in the early periods of life.

The effect of vaccination in lowering the general mortality of small-pox admits of a very simple illustration.

In 1781, 646 patients were admitted into the Small-pox Hospital, of whom there died 257, being at the rate of 40 per cent. In 1844, out of 647 cases, there died 151, or 23½ per cent.; but then, out of 331 non-vaccinated persons, there died 127, being at the rate of 39 per cent. We may learn from this, that small-pox lost nothing of its original malignity in the sixty-four years which elapsed since 1781. Vaccination obviously diminished, in a very remarkable manner, the average intensity of the disorder, and the rate of mortality (viz., from 40 to 23), but it admits of question whether it diminished in a corresponding ratio the absolute number of cases.

There died of small pox in London, in 1781, 3,500 persons. With a mortality of 40 per cent., the total number of cases occurring in that year would be 8,778. In 1844, the total deaths by small-pox in London and its environs were 1,804. This, at 23 per cent., gives the total number of cases 7,844. The difference in the amount of population at the two periods forbids any idea of accurate comparison, but still the approximation of these figures is remarkable.

The type of the disease proved very severe during the year 1844, especially during the last three months of the year. 13 cases occurred at the Hospital of petechial small-pox, and 18 where the disease was ushered in with high delirium. A great number of those who experienced secondary fever had severe, and too often destructive ophthalmia.

The general severity of the epidemic was displayed among the vaccinated. Out of the 312 comprised in *this* section of the admissions, 186 passed through the disorder in a well-marked form, frequently indeed modified and mitigated, as the disease progressed, but often occasioning much anxiety during the early stages.

126 cases were of that mild kind, distinguished in the Hospital books as the *variola varicelloides*, or the "*highly modified variola.*" With one exception all these cases occurred in vaccinated subjects, who bore on their arms *cognizable cicatrices*. These cicatrices were usually (though not invariably) of normal character, and for the most part they were two, three, or four in number. A few exceptions to this law may be worth naming.

1. Thomas Taylor, aged 18, admitted Oct. 13, had the varicelloid disease, with *one large wafer-like cicatrix*.

2. Sarah Franklin, aged 15, admitted June 13, had the mild varioloid. Her arm displayed *one irregular and oblong cicatrix*, evidently the result of a sloughy vesicle.

3. Charlotte Hands, aged 33, admitted Oct. 1, had the varicelloid disease, with two *superficial* cicatrices.

4. Jane Nicholls, aged 18, admitted Aug. 18, had the varicelloid disease. On her arm were three cicatrices, but so *faintly perceptible* that they must have been overlooked, had the eruption proved confluent.

5. William Henry King, aged 14, admitted July 29, had the highly modified disease. His arm exhibited two cicatrices, but they were *small and abnormal*.

Among the 312 vaccinated persons who underwent small-pox, 70 were vaccinated in London, 214 were vaccinated in the country (including Scotland and Ireland), 18 on the Continent and in foreign parts. Ten were unable to state where their vaccination was performed. Of those vaccinated in London, seven were vaccinated at the Small-pox Hospital, seven at the stations of the Royal Jennerian Institution, and two reported themselves to have been vaccinated at the two principal stations of the National Vaccine Establishment.

The seven cases vaccinated at the Small-pox Hospital bore upon their arms excellent cicatrices. Three of them had five scars, and one had seven good scars. They were admitted at the following ages:—1 at 14, 1 at 16, 1 at 17, 1 at 18, 1 at 19, 1 at 21, 1 at 25.

In six of these cases, the disease was modified. Two exhibited, on admission, the confluent character of eruption. One young person, Eliza Dossetor, admitted Sept. 9, (her arm exhibiting one perfect cicatrix), passed through the semi-confluent disease wholly unmodified, *in the very same room* where, sixteen years before, she had been vaccinated.

Out of the 647 admissions, two persons reported themselves to have been *inoculated* successfully for small pox in early life, but both cases were open to great doubt. They are as follows:—

1. Edward F. Wye, aged 10, admitted October 29, was stated to have been inoculated at seven years of age, by a woman at Deptford. Besides the primary pustule on the arm, he is said to have had eight or nine spots on the body. This boy died on the twelfth day of the confluent disease.

2. David Field, aged 21, admitted July 9th, states that he was inoculated when young in Edinburgh. He has two good cicatrices on the arm. The disease proved confluent and fatal on the 16th July. It is very unlikely that the inoculation of small pox should have been practised in Edinburgh in 1824, and the presence of *two* cicatrices, resembling those of cow-pox, confirms my suspicion of the truth of the story.

Several cases, admitted into the Hospital during 1844, presented features of individual interest. The following may be taken as examples:—

1. Elias Tookey, aged 38, a native of Gloucestershire, admitted May 31, had been vaccinated when three weeks old, by Dr. Jenner himself, at Berkeley. He had the *confluent modified* disease.

2. Sarah Robinson was admitted at the advanced age of 83. She had been exposed to the contagion of small-pox on many occasions during her long life, but had never taken it. She was seized with the premonitory symptoms of small-pox on the 2nd July, admitted into the Hospital on the 6th July, and died of the confluent disease July 10th.

3. Cornelius Peers, aged 18, was admitted December 21, 1844, having confluent small-pox unmodified. He was a native of the Island of Celebes, and had been vaccinated in infancy, by a native doctor, who had received intructions in the practice of vaccination from a Dutch surgeon, resident in

the Court of that island. Six very good cicatrices were apparent on the arm. For some time this young man's life was in danger, but he ultimately recovered, and was discharged cured, January, 1845.

4. Emmeline Eliza Richardson, aged 20, was admitted September 7. She had been vaccinated in the country when young, and had two excellent cicatrices. The disease assumed the varioloid form; and no danger was apprehended. On the 11th September, at 7 a.m., she was seized, for the first time in her life, with a violent epileptic paroxysm; succeeded by a long and formidable state of coma. She gradually recovered, and was discharged cured September 23.

5. Elizabeth Eagle, aged 33, servant, was admitted November 30. She had been vaccinated when six years old at Nayland, Suffolk, and bore upon her arm three excellent indented normal cicatrices. Fourteen years ago she was carefully *revaccinated* by a medical practitioner of the same place, without effect. She had small-pox in a confluent and highly aggravated form, and died on the 22nd December.

Of the twenty-four fatal cases after vaccination, the greater number (nineteen) were aged between twenty and thirty. One died aged forty-three.

Hitherto, but very few cases of small-pox proving fatal to young persons after vaccination have occurred, either at the Small-pox Hospital or elsewhere, and a general belief has prevailed that the interval from the period of vaccination to the attack was an important feature in determining the severity of the consecutive disorder. The epidemic of 1844 threatens to subvert this long-received opinion. The returns of deaths from the Metropolitan districts, for nineteen weeks of that year, were submitted to me by the Registrar-General, among which I detected more than twenty instances of persons of tender years dying of small pox after alleged, and, apparently, satisfactory vaccination. At the Small-pox Hospital, during the year 1844, one vaccinated person died at the age of ten, one at seventeen, and one at eighteen years of age.

A remarkable feature in the history of the Small-pox Hospital during the epidemic was the extraordinary increase in the applications for revaccination. Out of a total of 632 persons, vaccinated during the last quarter of 1844, 134 were revaccinations, many of them the brothers and sisters of parties then undergoing post-vaccine small-pox.

The proportion of successful to unsuccessful revaccinations was certainly much larger than I ever remember to have seen it before. In many instances the second process was in all respects normal, even though perfect and numerous cicatrices were observable on the arm.

In private practice I had occasion, during the year 1811, to see thirteen cases of *small-pox after vaccination*; of whom nine had the disease severely and 4 mildly. In *none* of the cases was there any obvious mitigation of the symptoms by previous vaccination. Three of them died, and ten recovered, —one with the loss of the right eye.

This detail of the very grave events which, under my observation, characterised the epidemic of 1844, suggests several important inferences. It shows us, in the first place, that small pox will spread far and wide, without any aid from artificial propagation. No person was inoculated in London in that year, yet never has small-pox been more widely disseminated. The disease, too, has prevailed, with variable degrees of intensity, in every county of England, quite as much since inoculation has been abolished, as it did prior to 1810.

We have seen that the numbers admitted into the Small-pox Hospital during the year, *with* and *without* preceding vaccination, are nearly equal. It has been made apparent by former experie both in civil and military life, as well as by the events of 1844, that small-pox, after vaccination, proves fatal at the rate of 7 per cent. Now, it is known, that the deaths by *inoculated* small pox are only 1-5th per cent., or 1 in 500. Coupling the low rate of mortality by inoculated small-pox with the fact of the general prevalence of the disease over the whole country, independent of inoculation, there seems no valid reason why we should not avail ourselves of a measure which, in former times, was so beneficially employed for the mitigation of small-pox. When favourable opportunities offer, we might subject vaccinated persons to the test of inoculation at that period of life (puberty) when experience teaches that the susceptibility of small-pox is most likely to occur, and when the risk from small-pox, if taken, is always least.

I have long been persuaded that the tying up the hands of medical men, and preventing them, by law, from adopting such a measure is injudicious, and the recent epidemics confirm me in the opinion. It is difficult to see on what grounds the proposal could be objected to by the warmest supporters of vaccination. If the operation be followed (as it in the case of my eldest son) by pustule without constitutional disturbance, the efficiency of vaccination is proclaimed, and the security f the individual placed beyond a doubt. On the other hand, if constitutional symptoms *should* arise, we may reasonably anticipate that the resulting disorder will be mild, and most probably of the mitigated or modified sort. But, whether mitigated or unmitigated, the disorder, if taken, would, under such an arrangement, be undergone at home under the care of parents, and at a period of life the most favourable of all others for the reception of small-pox, instead of its occurring casually in more advanced life, with less power of constitutional resistance, and at a moment, perhaps, of all others the most inopportune. Several instances have occurred to me of married women taking small-pox at the period of their confinement —of young women receiving small-pox after vaccination when they were on the eve of marriage; and of young men taking it at the very moment when they were embarking for India!

It has been argued, that in revaccination, we possess a corrective for any defect in the primary process, adequate to all emergencies. The results of the two recent epidemics do not tend to establish this opinion. Many cases have occurred of persons taking small-pox after attempts at re-vaccination,—sometimes successful, sometimes unsuccessful. The further proposal of establishing a perpetual series of revaccinations, at intervals of five, seven, or ten years, so as to keep the vaccine influence always alive in the system, is obviously inapplicable in practice on a large scale.

As the law stands at present in England, any parent is permitted to expose his child to the natural infection of small-pox by the lungs; but he is punished, if he submits that child to the milder mode of reception, through the medium of the cutaneous absorbents! To be consistent, the law should *compel* parents to vaccinate their children. The existing law is manifestly absurd.

Against all unqualified practitioners the law abrogating inoculation should of course be rigidly enforced; but an obvious difference exists between indiscriminate inoculation by itinerant quacks, and the careful performance of the same operation, in select cases, by competent persons. One improvement would *necessarily* result from such a relaxation of the law as I here contemplate.

No other means exist of testing the efficiency of new lymph than *inoculation*. Vaccine lymph has been taken from the cow and disseminated throughout the provinces of England, very frequently and widely during the last few years, but no attempt has been, or can legally be made, to ascertain the protective powers of each new stock. Further, cases occasionally occur where inoculation might properly be adopted in *preference* to vaccination, even in young persons. The following occurred at the Small-pox Hospital in the course of the late epidemic:—

Eliza Douglas, aged 25, was admitted on the 23rd December, 1844, having severe confluent small-pox. With her came her two children, Rebecca, aged 4, covered with a confluent eruption, and Fanny, aged 14 months, in perfect health. Had I been left to the exercise of my own discretion, I would immediately have inoculated the infant Fanny, and taken my chance of the *artificial* preceding and superseding the *natural* disease. Twenty-four hours, too, would thus have been gained. The law not admitting of this course, the child was vaccinated on the following day in five places. On the 31st of December five perfect vaccine vesicles were developed. On the succeeding day confluent small-pox appeared on the child, who died January 8th.

Case 2. Rebecca Stephens, aged 24, was received into the Small-pox Hospital on the 9th of November, 1844. She was supposed to have small-pox, but the disorder proved to be *measles*. Nov. 13, sixth day of eruption, she is convalescent from measles; on this day she *ought* to have been inoculated; but the law not allowing this, she was vaccinated in five places, and in eight days the vaccine vesicles were properly developed.

On the same evening, however, (Wednesday, Nov. 20th,) small-pox appeared, of the *semi-confluent* kind. The convalescence was very tedious, being protracted by considerable secondary fever. She was discharged cured Dec. 23rd.

After very careful reflection, for many successive years, on the occurrences taking place around me, I am driven to the conclusion, that while encouraging vaccination to the utmost of our power, we ought not to close our eyes to the benefits which may arise from combining with it the *occasional practice of variolous inoculation*. Restricted as it would be (and as it ought to be) to medical practitioners, no reasonable doubt can exist but that it would be used with caution and due consideration, and from such modified employment of inoculation I foresee the greatest benefit, and no danger whatever.

Vaccination has now a strong hold upon the public mind, and that hold it will retain, provided Medical men continue convinced of its protective power. Medical men should, therefore, be armed with all proper means for testing the progressive security of vaccination at different periods of life.

The conclusion to which I have come is, that the Legislature would act wisely in repealing that clause of the "*Vaccination Extension Act*" which prohibits *Medical men* in England from the practice of inoculation; and further, that the occasional testing of vaccinated persons (especially of those verging on the period of puberty) would be preferable to the practice of *revaccination*, and a useful addition to the system of *infantile vaccination*, which should be encouraged, and supported as one of the greatest blessings which Providence has vouchsafed to man. We christen a child in infancy, but we *confirm* him at the period of puberty. We should treat the body as we treat the soul. We should vaccinate in infancy, but we should confirm (by inoculation) at the age of 14. With the provision for adult inoculation which has been suggested, I can see no valid reason why the practice of infantile vaccination might not hereafter be made *compulsory*.

MEDICAL SCHOOLS AND UNIVERSITY TOWNS OF GERMANY.

By Dr. BUSHNAN.

(Continued from page 50.)

THE DIFFERENT CLASSES OF CIVIL PRACTITIONERS.

The body of men whom I am now to consider are perfectly distinct in their character from the hierarchy of the medical officials. Their position in society is in conformity with the Royal Decree of January, 1825, in which the prime mover seems to have been the celebrated Rust. They constitute four distinct classes:—1. Graduated civil practitioners (doctors.) 2. Surgeons of the first-class, or medical surgeons, not graduated. 3. Surgeons of the second class. 4. Military practitioners.

1. Graduated Civil Practitioners. These gentlemen are either general practitioners, or pure physicians, confining their practice solely to internal diseases. The medical functionaries are selected from this body.

The practitioners embraced in the second class are of an inferior caste; they require no University education, but must possess a competent knowledge of the more simple Latin authors, and the capability of correctly writing a prescription. The right to practise follows the State examination. The exercise of their functions is, however, limited, as they are not entitled to practise in any locality where there is a doctor of medicine. Should any one settle in such a place, he is obliged by law to confine himself to the practice of surgery. This system of a restricted and conditional class of practitioners, did not, as was easily to have been foreseen, work harmoniously; and, in consequence of their interference with existing laws, a decree was passed in 1837 denying them permission to establish themselves in large towns, excluding, them in short, from every place where there was already a doctor of medicine. In this way they were reduced to the condition of the country surgeons, who had been suppressed by an ordinance in 1825. Much disagreeable collision has resulted from the establishment of this class of practitioners, and there has been no small amount of ink shed. It is the almost unanimous opinion of the superior officers of the Ministry that these surgeons of the first class should be suppressed.

3. Non-graduated Surgeons of the Second Class.—No one can attain a title to this grade unless he has officiated three years as an assistant-surgeon in the army, or followed the course of a medico-chirurgical school during that period. His classical and general knowledge, moreover, must be such as give him a claim to be admitted to the third division of a classical college. He then acquires his licence to practise from a provincial medical college, after he has undergone an examination of a restricted character, excluding altogether the practice of medicine. Though at liberty to settle anywhere, the sphere of their practice is very narrow, as they are only authorised to perform phlebotomy and scarification, and apply leeches. They are not permitted to treat any internal disorders, and they are held amenable for the consequences of any operation they may perform. They do more, however, than the law allows them.

Surgeons of the first and second grade never can assume the rank of doctor without special authority from the Minister, and, even though they have obtained this step, they do not hold *status* with the graduated practitioners.

Besides these, there are other special grades of accoucheurs, dentists, and oculists. These are examined by the provincial medical colleges, and the dentists required to have served three years in the army as military surgeons.

This distribution or classification of the Medical Practitioners has been severely criticised and objected to by the most able authorities. It is contended, that the division of the art of healing into medicine and surgery is based on a principle totally false: and that the distinction of operations into serious and slight, for the surgeons of the first and second class, is ridiculous, and of no practical import.

MILITARY DOCTORS.

To these, as to everything that relates to the Military Profession, Prussia shows her wonted partiality.

In Berlin there are two preparatory Institutions, intended for those pupils who are destined for the army,—the Foundation of Frederic William, and the Military Academy. The pupils, on entering these establishments, engage, for each year of instruction, to give two years service in the army as surgeons.

The pupils of the Institute of Frederic William number about 1100, are supported at the expense of the State, and have their Medical education gratuitously; they also receive a small allowance for pocket money.

It is otherwise with the pupils of the Military Academy, as they pay for their board and lodging. They receive, however, their medical education free. By way of compensation, however, they are only required to serve one-half the time in the army.

The period of study in both Institutions is the same, four years. When this is concluded, and they have received the title of Doctor, they enter the Hospital of La Charité, where, under the name of station doctors, they perform all the duties of house surgeons or physicians. The number of those from the Military Academy who do this, is limited. Their period of service in the hospital is one year.

In the charge of each, there are usually betwee 40 and 60 patients, whom it is compulsory to visit four times daily—twice by himself, and twice in company with the Medical officer in attendance. He is required to preserve a succinct account of the history of each case, and those of more than usual interest are detailed in a monthly report No one is allowed to publish the history of the cases in any Medical Journal, the privilege being reserved to the head physicians and surgeons.

In addition to board and lodging, the station doctors receive a salary of about 14*l.* yearly. On leaving the establishment, they enter the military service as surgeons. Legally, the pupils of the Institute are bound for eight years' service, and those of the Academy for four, but they ordinarily serve only half that period. They are quartered in the different garrisons, and have about 18*l.* as yearly pay. Their rank is equivalent to that of sergeant-major.

The period of military service concluded, the surgeon has three paths, one or other of which he can select. He may remain in the army, and forthwith he assumes the title of battalion doctor; but there is no further advance for him; or he returns to the Institute of Frederic William, to officiate as a teacher there for some five or six years. Finally, he can quit the military service.

At the close of their service as teachers in the Institute, they re-enter La Charité, under the designation of staff-doctors; their position being intermediate, between the station-doctors, who are their inferiors, and the hospital surgeons and physicians. They lodge and board in the establishment.

From the body of these staff-doctors the regimental surgeons are supplied. The next step is that of Doctor of Division, which immediately leads to the grade of physician to the general staff, the highest point of military medical hierarchy.

To complete the military medical organisation, the surgeons of the regiment or battalion, (having received the consent of the commander,) have a soldier to act as a dresser in the garrison hospital, who boards and lodges in the hospital, and must at least be able to read, write, and cypher. At first, their duty is to prepare baths, and apply blisters [illegible]d moxas, and subsequently acquiring a little [illegible]owledge of anatomy, they assist in the application of bandages, and aid the apothecary to prepare the medicines. They rank as apprentices for the first two years. At the end of two or three years they are called surgeons' assistants, taking the military rank of corporal. When they have concluded nine years' service, they rank as sub-officer, and receive pay accordingly. And in common with all subalterns, [illegible]hey claim a right to some civil appointment, after [illegible]welve years' service.

They do not throw away the practical knowledge [illegible]hey have thus acquired on quitting the military [illegible]ervice; but, following the example of the surgeon of the first and second class, they engage in [illegible]llegal practice, and so become an additional source of inquietude to the regular doctors, and [illegible]nterfere with the constituted medical hierarchy.

[To be continued.]

HOSPITAL REPORTS.

KING'S COLLEGE HOSPITAL.

RE-SECTION OF THE HEAD OF THE THIGH BONE.

Understanding that Mr. Fergusson was to perform [illegible]his operation, about which our readers are aware so much discussion has lately occurred in our pages, [illegible]e visited the Hospital on Saturday last. We found [illegible] great number of medical men, equally anxious with ourselves to witness the nature of the case, as well as the operation, assembled, and great interest was evidently excited.

At two o'clock the patient, a boy of ten years old, was brought into the theatre, and placed upon the table, having previously been rendered insensible by chloroform. The diseased limb being uncovered, an unequivocal specimen of morbus coxarius in its last stage was presented. The head of the bone was dislocated on the ilium, and could be felt through an opening which had been made over it. A large circular sore also existed over the trochanter, which was prominently protruding. The limb appeared to be much shortened, and the knee thrown across the other.

Mr. Fergusson carefully examined the parts with his finger, and then commenced the operation in the following manner:—An incision, about four inches in length, was made over the head of the bone, and carried below the great trochanter; the soft tissues were dissected from the sides of the bone, and the knife cautiously carried behind its neck, separating, as much as possible, the soft parts; the limb was then carried inwards by an assistant, and the section made by a small saw, below the trochanter major, and that process, together with the head of the femur, removed.

The cotyloid cavity was then examined, for the purpose of ascertaining if there was any disease to be removed, but it was discovered to be filled up with a mass of soft tissue which had been thrown out during the course of the malady. Several small vessels required a ligature; the wound was brought together, and the patient removed to bed. After the removal of the bone, the limb could be brought down straight with the other.

Mr. Fergusson, in the course of some observations, stated this to be one of those cases which surgeons—in London at least—denominated Morbus Coxarius in its last stage, and that the little boy, who had laboured for eighteen months under the disease, was sent into the Hospital for his opinion as to the propriety of performing the operation of re-section of the head of the femur. When the patient was first brought into the house, it was evident that dislocation existed; there was a large open sore over the trochanter major, and a profuse discharge of matter coming from it, which had greatly debilitated him. In order to ascertain the precise condition of the bone, and also to give some relief to the patient, a counter-opening above the trochanter had been made, and the head of the femur exposed, lying on the dorsum ilii, and in the centre of a large abscess. The cartilage could be felt on the bone, but its structure was so softened, that it could easily be penetrated by means of a probe. This measure had given the child some relief, but little hopes of further improvement; Mr. Fergusson regarded the head of the thigh bone as a foreign substance, keeping up irritation; and as he could not ascertain that there was any disease within the pelvis, nor in any organ of the body, he, therefore, considered it best for the patient to give him the benefit of the operation.

He had performed it in the same manner as [illegible]hey had before seen; he had removed the trochanter as well as the head of the bone, not because there was any disease within that process, but, because he had found from experience, that the wound healed more readily, and less irritation was afterwards caused, than when it was permitted to remain. They had seen that the limb could be straightened after the diseased part was taken away, and they would be able to keep it in a good position by the application of a splint.

With respect to the condition of the acetabulum, [illegible]t was probable that in this instance disease had at one time been present; but in this, as in other cases, after dislocation had taken place, and the two surfaces of the joint were no longer in contact, a reparative process had followed, and the morbid action in the acetabulum had ceased.

There had been much discussion as to the propriety of this operation; it was a subject which admitted of, and ought to have, a fair and open discussion amongst surgeons; he looked upon the present case as one of great interest, and he hoped [illegible]hat it would turn out satisfactorily.

PROGRESS OF MEDICAL SCIENCE.

FRANCE.

[From our own Correspondent.]

The slight recrudescence of the cholera, alluded to in my last, has not yet given way. On the contrary, the disease advances, though so slowly as to excite little apprehension. The number of deaths, in the city is about 15 daily; in the hospitals the same. On the 20th, of 35 cases admitted, no less than 21 proved fatal. The total mortality recorded by the official journals amounts to 16,000 for Paris; but, as I have already observed, this estimate falls considerably short of the truth.

The temporary increase of the epidemic cannot be attributed on this occasion, at least, to the heat, for the weather is cold and wet, the thermometer being below 20° Centigrade.

M. Husson, Physician to the Hotel-dieu, has been raised to the rank of officer of the Legion of Honour, and several physicians, distinguished for their zeal during the epidemic, have been made knights of the same order. Nor have the students been neglected.

Three hundred had placed themselves at the disposal of the authorities, and rendered immense services in the capital and environs. Each is to receive a silver medal and some pecuniary assistance towards completing his education. Two decorations of the Legion of Honour are to be distributed amongst the *internes*. The announcement of these intended recompenses was made by Professor Berrard to the assembled pupils on Saturday last, and every one acknowledged that they have been well deserved. In England, governmental gratitude never descends so low, and an honorary distinction conferred on a medical man is rarer than a "black swan." Strange it is, that the least military nation of Europe should reserve all its honours for soldiers.

The disease continues to spread in the provinces; and it is worthy of notice, that, as in Paris, it appears to select large public establishments for the seat of its ravages. Thus at Tours, the epidemic is almost exclusively confined to the General Hospital and the Penitentiary. The number of deaths in the town do not exceed three or four a day, while more than 100 prisoners in the Penitentiary were attacked within a few hours, and of these eighty died shortly after the attack; the cases being all of the very worst description—*faudroyans*, as they are termed here.

I have been informed by several Practitioners, that the "sweating sickness" also has made its appearance at Paris, and seems to select those localities in which the cholera was most prevalent.

CHEMISTRY.

Every one must have made the remark, that for the last few years the French school of chemistry has remained almost inactive. If we except a few detached memoirs addressed to the Academy of Sciences by MM. Baresivil and Cahours, Laurent and Gerhart, we look in vain for any sign of progress in that once famous school. Pelouze and Payen, Batard, Peligot, Fremy, Thenard, *e tutt quanti*, are silent, if not absolutely idle.

The cause of this stagnation may, I believe, be in great part attributed to the *route* which one of our greatest chemists, M. Dumas, has pursued for so long a time, but which he seems to have suddenly and completely abandoned.

Who has forgotten the sensation produced here some twelve or fifteen years ago, when Dumas and Liebig made their triumphal entry into the Institute, announcing a scientific alliance between th chemists of France and Germany, for the discover of the mysteries of life and death? M. Dumas was the orator on that memorable occasion; and hi brilliant eloquence captivated even the reason o his auditors. The animal and vegetable kingdom were to be analyzed; their successive transformations under the influence of organic agents were to be discovered; and this done, the philosophers ha merely to reproduce them artificially.

But the alliance, alas! was short-lived, and soo gave place to bitter war between the illustrious associates. Abandoned by his German confederate, M. Dumas bravely entered on the campaign alone, and brought forth his famous theory of *substitutions*, astonishing the world by its flash, but ending suddenly in darkness and oblivion.

This, however, was merely a pastime for M. Dumas. He soon returned to the charge, and set out on a new voyage of discovery, in company with MM. Payen and Bouissingault. This time we were assured of success, and, for a moment, even the illustrious chemists just named laboured under the conviction that they were about to reproduce in their crucibles the mysterious process of digestion. They furnished the experiments—weighing, now an ox, now a goose; examining the *ingesta* and *egesta*—while M. Dumas furnished the discourses—discourses of surpassing interest, but leaving behind them little of greater value than the *egesta* of the experimentalists. Who can forget the effect produced when M. Dumas announced the definite triumph of organic statistics, and in a paroxysm of eloquence said: "Gentlemen, within three months this great mystery will be unravelled, and we shall then be enabled to furnish you with positive rules for the alimentation of the poor man and the prisoner, the sick and the working classes."

The promised announcement, alas! was never made; animals continued to digest in their former ignorance, and the poor to starve; while chemical combinations, rebellious to the new doctrine, obstinately arranged themselves under the antiquated laws of a Lavoisier, a Berthollet, or a Berzelius.

Since this defeat, M. Dumas has observed a dignified silence, and his retirement appears to have given rise to the torpor of the French School, already noticed. A state of repose has followed the excitement produced by the seducing promises of M. Dumas; but it is to be hoped that the grand conception of the master may not be abandoned on account of his eccentricities. He failed, it is true, to establish a link between inorganic and vital phenomena; but the discovery of M. Raymond shows that the mystery of life may be made visible even to the eye of man.

EXTRACTION OF SUGAR BY A NEW PROCESS.

The *Moniteur* publishes a report, by the Minister of Commerce, on a discovery made by a young Belgian chemist, M. Melsens, a pupil of M. Dumas, which appears destined to exercise a very high influence on commercial affairs.

M. Melsens, it is said, has discovered a mode of extracting sugar from beet-root and the cane, without having recourse to any of the present expensive processes. The yield of sugar is increased one-third for beet-root and a half for sugar.

The scientific men, to whom this important discovery has been communicated, speak with certainty of its success, and the French Minister of Commerce says, "In presence of this revolution, which is imminent, all industrial operations connected with the manufacture of sugar are suspended, and the natural course of affairs cannot be resumed until public opinion shall be enabled to decide on the value of the new process."

The Minister, therefore, proposes to appoint a Committee to examine M. Melsen's discovery; and, if the report be favourable, he intends recommending the National Assembly to purchase it for the benefit of the State. The Committee has been already named, and is composed of M. Dumas and Chevreul, chemists, the Director-General of the Customs, four sugar manufacturers, and six members of the Legislature.

EFFECTS OF REMEDIES APPLIED DIRECTLY TO THE BLOOD.

M. Flourens has recently made some experiments on the effects produced by various substances when injected into the arteries. The results obtained by the learned physiologist are novel and entertaining.

They show that the substances employed may be distinguished into four classes: 1st. Those which act on sensibility; 2nd. Those which act on mobility; 3rd. Substances which produce muscular paralysis with relaxation; and 4th. Substances which give rise to muscular paralysis with rigidity.

The substances of the first class, or those which destroy sensibility, are the powder of liquorice, oak-bark, and cicuta; valerian, belladonna, pepper, and naphtha oil.

The substances of the second class, or those which destroy mobility, are sulphuric, acetic, and oxalic ethers; alcohol, sulphuric acid, tincture of camphor, chloroform, and the essences of bergamotte, cloves, mint, rosemary, fennel, &c.

The third class comprises the three ethers just mentioned, alcohol, sulphuric acid, ammonia, camphor, naphtha, oak bark, and liquorice.

In the fourth class, or that of substances producing muscular paralysis with rigidity, we have chloroform, and the essences of turpentine, bergamotte, cloves, mint, rosemary, and fennel.

Such are the facts deduced from the experiments of M. Flourens, and they give rise to many interesting questions. Why, for example, do certain substances act on the mobility, while others influence sensibility only? Why do some produce paralysis with relaxation, while others give rise to paralysis with tetanus? Why does naphtha act on the nerves in a manner analogous to the powders and camphor like the others? Why does chloroform act on the muscles like essences, while the ethers have an action analogous to the powders? We must confess our complete ignorance on these points; but it is not the less remarkable, that while some of those substances which produce paralysis with relaxation, act on the sensibility, and some on the mobility, All those substances that produce tetanic paralysis, act on the anterior roots of the spinal nerves.

TREATMENT OF GRANULAR OPHTHALMIA.

Some interesting, and at the same time decisive experiments were recently made at the Military Hospital of Bruges, to determine the relative values of nitrate of silver and acetate of lead in the treatment of the above mentioned disease. They prove the incontestible superiority of the acetate of lead.

This remedy was first introduced into practice by M. Buys, I believe, of the Bruges Hospital. His mode of applying it is as follows:—The neutral acetate of lead is reduced to an impalpable powder, and applied to the eyelids by means of a very fine hair-pencil moistened with water, and then dipped in the powder. From one grain to one grain and a-half, is sufficient to cover the whole inner surface of one eyelid, over which it is uniformly spread. After two or three applications, the granules disappear, and several examples of a prompt cure are related by Dr. Cunier, in cases which the surgeons id acknowledged to be rebellious to nitrate of silver. The application of the lead is likewise much less painful.

VAPORIZATION OF CHARCOAL.

M. Despretz, who had been making some experiments on the fusion of substances by the united heat derived from a lens, the blow-pipe, and electricity, announced to the Academy of Sciences that he has succeeded in converting carbon into vapour, by means of an electrical machine, containing 496 elements. It appears to be easier to reduce carbon to vapour than to melt it; and the experiments of M. Despretz lead him to conclude that any attempt to melt this refractory substance should be made in nitrogen gas, in metallic vessels, and under a pressure greater than that of the atmosphere.

SCOTLAND.

(From our own Correspondent.)

SCIRRHOUS INDURATION OF THE PERITONEUM.

At the Pathological Meeting of our Medico-Chirurgical Society on the 18th current, Dr. W. Gairdner, Pathologist to the Infirmary, exhibited an interesting specimen of scirrhous induration of the peritoneum. The case occurred recently in one of the clinical wards under Dr. Alison. Before death the patient had a cadaverous look, and altogether the appearance of suffering under considerable organic disease. He was affected with jaundice of a green tint; there was pain on the right side, and also tumefaction; but neither of these symptoms

seemed distinctly referable to the liver. At the last, fluctuation in the abdomen became perceptible. On inspection after death, there was found a considerable quantity of blood in the abdominal cavity; the peritoneum was covered with a layer resembling inflammatory exudation, but which really was nothing more than the decolorized fibrine of a part of the extravasated blood. The peritoneum, as the specimen showed, was hardened and thickened, particularly in the appendiculæ epiploicæ of the right side, in the mesentery close to the intestines, and in the omentum minus adjacent to the stomach. Minute tuberculated spots occurred in many places, in particular throughout the pelvic peritoneum. There were also numerous ecchymoses, and these also were conspicuous in the pelvic peritoneum. There was no manifest source of the hæmorrhage, and no sign of the rupture of any considerable vessel was obtained by the injection of the aorta or of the vena cava. The mesenteric glands, though so close to one of the principal masses of the disease, were wholly unaffected, as were the liver and the other glandular organs of the body; indeed, nowhere else were there found any marks of carcinomatous degeneration. The microscopic examination of the morbid texture in the appendiculæ epiploicæ, where the disease seemed to be most developed, gave no satisfactory results, apparently owing to the excessive accumulation of fat; but in the tuberculated spots of the pelvic peritoneum, distinct cancerous corpuscles were discovered. Dr. Gairdner referred to a case of soft cancerous degeneration of the peritoneum which had fallen under his observation, where, as in this instance, the mesenteric glands were unaffected, though close to the seat of the disease. Mr. Syme, who was in the chair, mentioned some particulars of a case in which he had been called on to tap the abdomen, which turned out to be an instance of effusion of blood into its cavity, connected with disease of a like nature.

DISSECTING ANEURISM OF THE AORTA.

Dr. W. Gairdner next brought forward a remarkble example of dissecting aneurism of the aorta, which had occurred in the practice of Dr. Sidy. The patient, a man fifty-four years of age, had been given to intemperance. He had been drinking for two days, and on the third, when going to his work, he felt ill. The first symptoms, pain and the like, were referred to the stomach; and as he had suffered under a stomach complaint from early youth, his illness does not appear to have caused much alarm. When Dr. Sidy saw him the pulse was 75, and soft; the heart's action feeble, and no bruit could be heard; there was no palpitation, nor were any indications of disease of the heart or of the great vessels gathered from the account he gave of himself. Dr. Sidy proposed to examine his chest more particularly at his next visit, but before he returned the patient had died suddenly. On opening the body, blood was found within the pericardium in very large quantity. Both sets of valves and the heart itself were quite healthy, and no appearance of disease was found till a large portion of the aorta was removed. On the interior surface of this vessel, a short distance from the heart, was discovered a transverse slit, including not much less than its whole circumference; through this slit the blood had penetrated into the substance of the middle coat, between the layers of which it had made its way so as to escape through the outer coat into the pericardium just above the right auricle. In the coats of the artery itself there was no atheromatous or other perceptible kind of degeneration; it seemed to be as nearly as possible in a healthy state. Dr. Gairdner entered, at some length, on the consideration of several of the most remarkable cases of dissecting aneurism of the aorta, already recorded, and after frequent reference to Dr. Peacock's paper, to Dr. J. Davy's experiments on the power of arteries to bear forcible distention without rupture, and to the views of other authorities on this subject, he came to the conclusion that dissecting aneurism of the aorta probably originated much more frequently from external violence than had hitherto been admitted. And though there was no evidence of violence in the case before the Society, yet, as the man had been intoxicated for a good many hours shortly before his illness commenced, and as there was nothing in the state of the coats to account for the laceration, and more especially for its great extent, he was disposed to think that a fall, or some other kind of external force, had been concerned in the rupture of the vessel. A discussion followed, turning chiefly on the comparative facility with which the coats of the arteries and the layers of the middle coats separate from each other, and on the power of the arteries to resist rupture from forcible distension. Mr Struthers insisted on the facility with which the layers of the middle coat of the aorta may be separated from each other in the dead body, and instanced the common case of the giving way of the aorta, just above the heart, on the injection of subjects for anatomical purposes. Mr. Spence thought Mr. Struthers made some exaggeration as to the former point, and Mr. Goodsir considered the rupture of the aorta under the injections practised in anatomical theatres as the effect of degeneration of its coats. Mr. Syme agreed with Mr. Goodsir on this point, but remarked on the considerable influence of external violence in giving rise to aneurisms, and referred to the disease by which Mr. Liston was cut off, as having had its origin in a blow. Dr. W. Gairdner, in reply, insisted on the great difference on the coats of an artery between the reaction following a sudden jerk, and the effect of the slower distension, practised in Dr. John Davy's experiments, and in the injection of subjects for anatomical purposes. Mr. Goodsir admitted the distinction, and referred to the frequency of rupture of the aorta, near the heart, in horses, killed by over-fatigue. Reference was also made to the rupture of the left ventricle in hares hunted to death.

RESTORATION OF THE UNDER LIP.

Next was introduced to the society a man whose under lip Mr. Syme had recently restored. The lip had been removed by Dr. James Duncan, and as the patient suffered considerable inconvenience, owing to the great deficiency of the lip, Dr. Duncan had recommended him to Mr. Syme for operation. The restoration was quite complete; there was nothing that could be called deformity; the man spoke with ease and distinctness, and expressed himself very grateful for the relief afforded to him by the operation.

SUDDEN DEATH FROM PERFORATION OF THE STOMACH.

Dr. Macauley then exhibited the stomach of a female who had been cut off suddenly a few days before, in consequence of the escape by a perforation of alimentary substances into the abdominal cavity. Besides the perforating ulcer, there were other marks of ulceration in progress, and also cicatrising and cicatrised. The deceased was a house-maid subject to stomach complaint; she had been indisposed for a few days. On the morning of Sunday, the 15th, she was seized with pain in the lower part of the abdomen, along with vomiting, while she was carrying coals to the kitchen from the area cellar. When seen soon after, the same symptoms continued, and there was great prostration, but no distinct symptoms of inflammation arose. No remedy afforded any material relief. The vomiting at last subsided, and she gradually sunk sixteen hours from the commencement of the attack. Dr. Macauley remarked, that the patient was, from the first, pale and anæmatous looking. The only remarkable appearance besides in the body was the unusual size of the thymus gland.

CONNEXION OF UNUSUAL SIZE OF THE THYMUS GLAND WITH ANÆMIA.

In illustration of the connexion between the anæmatous state and unusual size of the thymus, Dr. W. Gairdner exhibited a drawing of the neck and front of the thorax, showing a particularly large thymus in a female twenty years of age, from a case of an anæmatous character, which had recently occurred in the Infirmary; and several other cases of the same kind were referred to.

ANOMALOUS COURSE OF THE ARTERY OF THE BULB.

Mr. Spence then exhibited an interesting dissection of the pelvic arteries to illustrate an undescribed anomaly of the artery of the bulb, which took such a course that it must necessarily have fallen under the knife, during the division of the urethra in lateral lithotomy. The anatomists present acknowledged that they were unacquainted with the anomaly pointed out. The members of the Profession, who take an interest in such deviations from normal structure, will, doubtless, ere long, have an opportunity of studying Mr. Spence's own account of this matter.

BLOODY CYST OVER THE TUBEROSITY OF THE RIGHT ISCHIUM.

Lastly, Dr. Dunsmure exhibited a cyst of considerable size which he had recently removed from over the tuberosity of the right ischium. The contents were bloody, not unlike the fluid in hæmatocele. The man was a weaver; and the tumor had caused him so much inconvenience, that he had cut a hole in his bench to relieve it from pressure. The microscopic examination of the fluid had detected nothing more than the elements of the blood,—there was, however, an unusual abundance of white corpuscles. In connexion with the character of its contents, Mr. Syme remarked on the little progress which the pathology of hæmatocele was making.

Several articles made of Gutta Percha, sent by a manufacturer in Edinburgh, were exhibited,—ear-trumpets of various forms, and utensils for the use of the sick room.

This being the last meeting of the Society till the beginning of November, the President made a short address, noticing, in particular, the success of the new plan of having separate Pathological meetings, as holding out the prospect of still more important communications in future sessions.

TO SUBSCRIBERS.

Subscribers in want of any of the back Numbers are recommended to complete their sets. Cases for binding the volumes, price 2s. each, are now ready for delivery.

New Subscribers will oblige by forwarding their Names direct to the Office, 147, Strand, or to the News Agents or Booksellers. All Post office Orders should be made payable to the Publishers, WM. S. ORR AND CO.

THE MEDICAL TIMES.

SATURDAY, JULY 28, 1849.

THE Profession of Medicine is about to have another insult added to the number which have already been heaped upon it; and the hopes which we had formed, that justice would be done to the public in the administration of Health Laws are, for this Session, we fear, doomed to disappointment.

Since the formation of the General Board of Health, under the Public Health Act, ten months ago, the whole Professional, and a great part of the general Press, have recorded, in terms of no measured indignation, the gross injustice of confiding to men, utterly ignorant of the machinery and working of the human frame, the laws which are to govern matters affecting the health of a great part of our town population.

The specious plea of the Board being a Board of *Works* and not a Board of *Health* was put into the mouth of the Noble Lord who presides over the Board; but we venture to say, that neither Lord Carlisle nor Lord Ashley will be

found to stand up in either House of Parliament and maintain the silly and ridiculous pretension.

What are the facts with regard to this Act? Why, that the whole professional duties strictly appertaining to medicine—and they are very numerous—must either be discharged by Lords Carlisle and Ashley, and Mr. Edwin Chadwick; or else those noblemen and that gentleman must seek for the information necessary to guide their counsels—which we believe they must now acknowledge they cannot possibly do without—in some underhand way, and from some unrecognized quarter.

What! is this all the acknowledgment by a liberal Government of the great services and vast sacrifices which have been rendered to the cause of public health by medical men? Is this the paternal care manifested by a Government professedly solicitous about the physical welfare of the masses of the poor who dwell in towns? Certes! to turn the Profession adrift with a cold 'thank you," for being so convenient and obliging a ladder by which others might safely and comfortably settle themselves in power, and to hand the public over to men who acknowledge themselves ignorant of the special question of Public Health, is an extraordinary method of exhibiting gratitude, and of promoting the public welfare.

It is impossible that the Profession can submit to this degradation, or that the public can endure this flagrant violation of their rights. Hitherto we have been silent, because we wished to believe that the force of circumstances alone had prevented the Government rectifying the false position in which they were last year placed by the opposition to the Health Bill in the House of Commons; but when an opportunity is afforded of rectifying the absurdity of the late Act by the amended Public Health Bill now before the House, and when we find that no attempt is there made to remedy the gross outrage on the Profession and the public, so loudly complained of, we cry shame to that Government which is so insensate to its own honour and the public welfare—which is so indifferent to the common weal, that it neglects a simple means of conferring a great public good, or is so miserably wanting in honest manliness as to yield its convictions of what is right to the stolid obstinacy of a dull-pated country gentleman.

To state that the Government are indifferent to this question may not be far from the truth; but that they are not indifferent to the loudly manifested voice of the public we have seen and know. Let, then, the Profession be aware, that every Health Officer to be appointed under the Health Act is to be subject to the approval of, (how otherwise than by examination?) and to be entirely regulated in the discharge of his duties by, the General Board. Let it reflect, for a moment, on the position of the present Poor-law Medical officers, and then determine whether another such system of extra-Professional Government, and Departmental disregard is to be lightly submitted to.

So far as the Profession is concerned, no greater misfortune can befal it than that the General Board should become recognised as a Government Board of *Health*, and that Medicine should be contemptuously ejected from it. In the old Institutions of Medicine many a long day's battle is yet to be fought, before the just claims of Medicine upon the State can be recognised, or its Professors assume their legitimate position in relation to the State. But in Public Health the cause is young, and unhampered by corporate jealousies, or the errors and prejudices of former times. It stands out in bold relief, a Medical Measure—suggested by Medical Men—fostered by Medical Men—upraised to its present position by Medical Men—and, it is not too much to say, only correctly appreciated, in its vast bearings on the welfare of the community, by Medical Men. Is it too much to ask, that a measure so essentially medical in its origin, in its progress, and in its application, should be worked by medical men? or is it calmly to be tolerated, that a great cause, gained through the indefatigable exertions of the Medical Sanitary Reformers, is to be misdirected, endangered, and sacrificed through the Ministerial weakness or the dead weight of a single oppositionist?

There is not a town or village in England in which the question of Sanitary Reform has not been agitated. Neither is there one, where a Medical Man can be found who does not feel that his interests and the interests of the public have been shamefully sacrificed by the Government. We will not heap blame on Lord Ashley, the representative of the Board in the House of Commons, for this disgraceful disregard, for we know him to be thoroughly open to the truthfulness and the justice of the cause we now advocate; and we would implore His Lordship even now to do battle against the intolerant bigotry and stupid obstinacy which oppose his manly efforts in this great cause of the People and the Profession. Success may yet crown his efforts:—defeat will not lessen the claim he has on the respect, esteem, and confidence of the public.

Whatever be the result, the Profession and the public have now entered upon the question, and for ourselves, we will not cease to agitate it till justice shall have been rendered.

ON THE PRINCIPLE OF THE MORAL TREATMENT OF THE INSANE.

'Tis the cause of man;
There dwell the most forlorn of human kind.

LURID as the atmosphere of the political horizon shone over the European Continent when the Saturnalia of the Revolution were enacted in France, there were still redeeming traits in the unsullied devotion of the Swiss to the Throne; of the followers of Larochejaquelin in La Vendée; and, even amid all the bloody scenes which the Place Louis Quinze hourly witnessed, a revolution of a very different character was going on, silently, even in the very centre of Paris, of which the benefits will be experienced by the latest posterity, and which claims the grateful acknowledgments of every inhabitant of the civilized globe. Prior to that period, the unfortunate lunatic was chained to the earth in his solitary cell, like a wild beast of the forest; and at times—we shudder to relate it—punished by stripes and blows from ignorant, perhaps well-meaning, but brutal keepers. This barbarous system of coercion was enforced everywhere, and even yet obtains in some remote and semi-civilized states.

The enlightened Pinel, in the year 1792, first struck the fetters from the maniac's limbs. As it was no less happily than truly said of Franklin—

Eripuit cœlo fulmen, sceptrumque tyrannis;

so Pinel restored the lunatic to the freedom of his limbs and to reason—and this was the dawn of the new, or moral management of the insane.

"In his visits to the Bicètre, where the lunatics were confined, Pinel was accompanied by the benevolent Coulon, who appears, however, rather to have been forced than persuaded into the measure, and whose reluctance was increased when he encountered the horrid noises and wild aspect of the miserable beings upon whom the experiment was about to be performed. 'Do with them what you please,' said he to Pinel, 'but I fear you will be their victim.' Happy in having thus his wish granted, no other reply was made by Pinel, than immediately to commence his plans by getting in readiness as many straight waistcoats as might be requisite, instead of the chains hitherto in use.

"For the experiment twelve lunatics were selected, one of whom, equal to any in ferocity, was an English officer, the particulars of whose history were unknown, save that he had been in fetters for forty years; and further, that he had, in one of his paroxysms, inflicted a fatal blow on his keeper; which deed, of course, was an apology for a greater degree of restraint being adopted in his case, and reasonably enough made strangers, or even the keepers, more than usually wary in approaching him. Entering his cell without attendants, and speaking gently,—'Captain,' said Pinel, 'I will order your chains to be taken off, and give you leave to walk in the court, if you will promise to behave well, and not to injure any person.' 'Yes, I promise,' was the reply, 'but you only laugh; you are all too much afraid of me.' 'There are six men at my command, if necessary,' rejoined Pinel; 'but believe my word, I will give you liberty, provided you put on this waistcoat.' The offer was silently and cheerfully accepted. The keeper retired, and the door of the cell was left open. After several attempts to raise himself from a position which had so long cramped his limbs, and having partly succeeded in managing his equilibrium, the Captain at length tottered into the free air, where, looking up to the sky, he cried out, with enthusiastic delight, 'How beautiful!' During the rest of the day he moved about constantly. In the evening he went voluntarily to his own cell, where a better couch than he had been accustomed to was prepared for him; and during two years afterwards, he was not only undisturbed by such paroxysms as he had formerly experienced, but rendered himself serviceable in the management of the patients."

The words of our metaphysical poet seem to convey an idea of the wretched state of the human mind, thus "cribb'd, cabin'd, and confined."

Each pure and natural outlet shrivel'd up
By ignorance and parching poverty,
His energies roll back upon his heart,
And stagnate and corrupt, till, changed to poison,
They break out on him like a loathsome plague-
spot.
Then we call in our pamper'd mountebanks.
And this is their best cure!—uncomforted
And friendless solitude, groaning, and tears,

And savage faces, at the clanking hour,
Seen through the steams and vapour of his dungeon
By the lamp's dismal twilight! So he lies
Circled with evil, till his very soul
Unmoulds its essence, hopelessly deform'd
By sights of ever more deformity.

This, then, was the first step; and a bold one, too, it was, that completely revolutionized the treatment of the unhappy insane,—which established a system of treatment for them founded on reason,—not on brute force; and the result of which now shines before the whole world in the moral management of the insane, and also, at the same time, evinces the soundness of the principles on which it is based, in the malady, under the new method of treatment, not showing itself more intractable than any other disease which is incident to the human frame. I may, perhaps, be of little moment what theory be proposed of the success of this line of treatment; for in the present day, whatever theoretical views we may support generally, we are most practically utilitarian ultimately.

By the term, "moral treatment," is usually understood all those means and arts by which we endeavour to restore the reason to its wonted due balance in the economy of the animal body —without the aid of medicines—or, we might say, with a noble bard, though said and sung in another sense,—

Can all saint, sage, or sophist ever writ,
People this lonely tower, *this tenement refit!*

the answer to which compass in the "moral management." The essentials of which are, *Isolation, Regularity,* and *Order;* but, above all, a due and well-organized system of *manual labour,*—or, to speak generically,—*physical fatigue.*

Assuming the mind to be immaterial, it is somewhat precarious to pronounce on what principle the so-named moral treatment produces its effects. On the opposite hypothesis of the nature of the mind, it would not be difficult to render some reasons sufficiently plausible and explanatory of the curative effects of the method of treatment; but the genius of our philosophy does not incline us to the latter hypothesis, though we admit the apparently very cogent arguments that have been adduced in its support.

A little examination into the essential features of Insanity may not be inappropriate, as introductory to the explanation we would respectfully submit: on this we shall be as brief as possible. Whatever definitions may have been offered on the subject, it is tolerably apparent, even to a superficial observer, that there is a want of control in the regulation and succession of the thoughts; which deficiency in the intellectual operations may affect all subjects indifferently, or may be limited and restricted to one idea. The precursory signs of the affection are all such as indicate an unsettled state of the physical and mental powers; the patient feels uneasy in one position, which he immediately changes for another, and this he as soon exchanges for a third, with as little reason as he made the first movement.

Quod petiit spernit; repetit, quod nuper omisit;
Æstuat et vitæ disconvenit ordine toto?
Diruit, ædificat, mutat quadrata rotundis.
Insanire putas solemnia me.

These symptoms, varying in different individuals, may continue for a longer or shorter period ere the open maniacal paroxysm break out,—the symptoms of which it is not requisite to detail here with the object we have in view.

Now, it has been ascertained by an accumulated series of observations, derived from all countries, and from all denominations of practitioners, that the malady yields rapidly, to a sound and duly organised plan of physical labour.

What, then, is there common to the mind and physical labour? Is it that the power which is expended in the one is so much withdrawn from the other, and proportionably the mental operations are suspended? This might seem a very obvious and natural mode of explaining the circumstance; but it fails in this, that it renders no reason whatever of the change in the train of ideas—it merely diminishes the amount of them (if such a physical form of language be not inadmissible.)

We conceive that the explanation rests in this, that, (arguing on the idea of the immateriality of the mind, and *à fortiori* the theory will equally hold good on the hypothesis of an unmixed materialism), there is undoubtedly a *somewhere* whence volition emanates to direct and control all the voluntary muscular movements, and equally coincident with this must be the volition by which we regulate or will the succession of our thoughts or ideas.

The will which determines the one, equally must preside over the other. There cannot be one will to direct muscular movement, and another to control thought, otherwise the unity of our consciousness could not for a moment subsist. First, then, as the power of the brain must be exhausted by the physical action long-continued and enforced, there will naturally be in that ratio a diminution of *thinking.* But this cannot take place without these morbid associations of thought becoming more or less broken in upon; and, as the force of these new morbid associations is according to a general law, always weaker than the associative relations of the older successions of thought, the latter eventually prevail.

The mental volition, as opposed to the physical, which regulates all the voluntary muscular movements, is not in due harmony; but a more than usually systematic plan has been adopted through the physical exertions the patient is constrained to make;—a firmer tone is thereby imparted to the volition generally, and, consequently, the aberrant fancies of the brain, which came "like shadows, so depart," and leave the mind of the patient in the wonted clearness and perspicacity of all its powers.

The direction, then, and regulation of the volition, so far as it is the controlling agent of the muscular movements, reduces the agent of volition, considered as an integrant part of the intellectual functions, to a more subdued state, and, by directly acting on one tissue of animal life, brings it generally into a more equable and harmonious, and more consistent mode of action; and, if it bring one most important operation of its functions into a regular and normal action, this healthy disposition will naturally be imparted to those other functions which it influences, actuates, and even may be said to rule. Indeed, this cannot hold otherwise than we have stated, if our postulate, that volition is one and the same, be conceded. To this it might be replied by some, that often the disease continues notwithstanding the healthy restored state of the muscular system. But it does not follow that volition may not be interrupted, in so far as the intellectual powers are affected, while the *physical* volition may exercise all its functions in complete perfection and harmony. The opposite occurs, we know certainly, where we witness daily the mind in the full exercise of all its intellectual powers, while the muscular system in different parts of the animal body, and in different degrees, is affected with palsy.

THE OPERATIVE SURGERY OF JOHANN FRIEDRICH DIEFFENBACH.

Edited by Dr. BUSHNAN.

(Continued from page 58.)

6. The extraction of foreign bodies from the cavity of the mouth and gullet.

Foreign bodies become fixed in the mouth only after having penetrated the mucous membrane, and are easily removed. When situate in the fauces or gullet, they create intolerable irritation, and eventually inflammation, if of a sharp or acrid description. Their immediate removal is, therefore, indispensable. Where there is a prospect of this being accomplished without operative interference, an endeavour may be made to provoke vomiting by thrusting down the end of a feather dipped in oil; if the patient has the power of swallowing, an emetic may be exhibited by the mouth, or, under urgent circumstances, injected into a vein. This treatment can apply only to small substances, for, if large and firmly impacted, the gullet may be ruptured. In all examinations with instruments, the tongue ought to be depressed to the utmost.

The body in question must either be withdrawn, or hurried into the stomach. The first course is the best, the last often dangerous. Venesection is occasionally indicated. Should everything fail, œsophagotomy is the sole alternative.

The substances which lodge in the fauces are generally small and pointed, such as fish-bones and needles, most frequently the former. The patient being seated, is directed to gape and make a deep inspiration, whereby the velum is elevated and the surgeon enabled to detect and extract the bone with a forceps. A lady, after eating some cake, suddenly shrieked with pain. I could perceive nothing about the neck, but on carrying my forefinger to the back of the tongue, brought away a long thick bristle, which lay archwise across.

Foreign bodies observe in their transit certain *stations* at which they halt; thus, in the pharynx behind the thyroid and cricoid cartilages, in the beginning of the gullet, or at its lower end, close to the diaphragm or cardia. They seldom stop at the middle of the gullet. If very large, they may cause suffocation—thus a large piece of meat, a hard-boiled egg, a pear, a chestnut, have each proved fatal. Guattani witnessed the most frightful death ensue from a chestnut; the part of the gullet at which it stuck was gangrenous. Spiritus saw the same result follow the swallowing of a five franc piece, which perforated the gullet above the cardiac orifice. Needles, inadvertently swallowed, pierce sometimes the gullet or stomach, advance by the aid of suppuration or otherwise towards the surface, and either escape spontaneously, or through incision. Lyson observed a case where three needles that went in at the mouth came out at the shoulder; I have known one issue at the arm.

The procedure must be modified according to the nature of the substance. None but a bungler would attempt to disgorge a piece of meat sticking at the cardiac opening, or urge on a fragment of glass from the gullet into the stomach. External pressure will suffice for potatoes or plums when stuck in the throat.

For the withdrawal of needles, fish bones, and the

like, there is no better implement than a large goose or swan quill-feather, with the barbed portion ruffled, and imbued with oil. The patient sits with his head leaning upon the breast of an assistant, while the surgeon lowers the tongue, then introduces the feather, with its concave side downwards, into the throat, turns it rapidly round, and draws it out. The popular practice of swallowing a crust of bread is sometimes availing, but may also increase the peril when arrested above the bone. A sudden slap on the back is by no means a bad plan, when the substance is large and obtuse. It is preferable to that of setting the patient on his head, as was done in the instance of Mr. Brunel, to promote the expulsion of the half sovereign piece.

The principal instruments employed for the present purpose are of the description of forceps. Dupuytren advises, as a preliminary step, the introduction of a gum elastic tube, surmounted with a silver ball, in order to ascertain the position of the foreign body. This, however, is superfluous, and will tend, moreover, to augment irritation. Cooper recommends the forceps of Weiss. The so-called leaden hammer of earlier writers consisted of a lead ball attached to a string, which was let down the throat, and pulled up again. Mesnier's lead hammer was of an olive shape; Petit's was equipped with a wire instead of a string. Petit used besides a metal noose fastened to a whalebone stem; Fabricius Hildanus a many-holed silver tube provided below with a sponge. The double ring of Graefe attached to the end of a rod of whalebone with a steel spring, is very convenient for taking pieces of money out of the throat. The customary instrument, termed *répoussoir*, or probang, namely, a bit of sponge as big as a walnut stuck to the end of a whalebone, is generally useful, either for entangling fish-bones and the like, or propelling large round substances. My own procedure is as follows: if the body be small and sharp, I employ the oiled feather above described. An oiled wax taper, passed down to the cardiac orifice, has proved serviceable; for, as soon as withdrawn, the body has been rejected. If the body be large, as a portion of flesh-meat adherent to a fragment of bone, I use a lithotrite with an imperforate scoop, and rather straight. The instrument is introduced with the blades closed, until it arrives at its destination, when these are to be separated sufficiently to grasp the substance, and, after a few gentle turns, withdrawn.

When there is impending suffocation from the presence of very large bodies impacted in the throat, Habicot enjoins tracheotomy before resorting to opening the œsophagus. I have never been compelled to this extreme measure. The most difficult thing to deal with are sets of false teeth when swallowed. I once relieved an old lady in this predicament by means of my fingers. On several occasions I have removed, with curved polypus forceps, from three to four teeth attached to a gold plate, and which got accidentally into the throat; once, by the aid of an emetic, as a last resort, a set of four teeth very deeply located.

In all these operations the patient is to be in a sitting posture; the head properly supported, the mouth rinsed with tepid water, tepid water mixed with white of egg taken as a drink, and the instrument smeared with white of egg rather than with oil.

7. Of Foreign Bodies in the Stomach and Intestines.

Foreign bodies may accumulate to enormous loads in the stomach before they endanger life. Fournier mentions a galley-slave who, after swallowing for years all sorts of extraneous substances, ultimately died of ileus. In his stomach were amassed twenty-eight bits of wood, a few small pewter spoons, several nails, buckles, weighing altogether one pound ten ounces. Bjerlander relates the instance of a man who swallowed a great many copper coins, a pocket-knife, and a steel for striking fire all of which were, however, rejected. Needles, bones of fish and of small poultry, are sometimes voided with impunity, at other times detained, perforate the tunics of the stomach, or the intestines, and migrate towards the surface, the track which they permeate being progressively closed as they advance. Small pointed bodies are found in the most unaccountable localities. Heim, the younger, records several instances of fragments of bone, grains of corn, and the like, which he detected in the *appendix coeci vermiformis*. I once met with a fish bone, half an inch long, in that situation, while examining the dead body of an aged female. I have not unfrequently seen fish bones and sharp osseous spiculæ discharged from fistulous openings about the verge of the anus, which had evidently perforated the rectum anteriorly to the sphincter, and given rise to fistula.

Leeches occasionally find their way into the stomach, and fasten themselves to its inner membrane. Numerous minute leeches were discovered in Egypt by Larrey in the stomachs of soldiers, who had died in consequence. When this happens, the patient ought to drink a quantity of strong solution of common salt to destroy the annelid, and afterwards an aperient dose of sulphate of magnesia to bring it away from the bowels.

When the substance remains, even after free vomiting has been induced, large quantities of white of egg ought to be administered either directly by the mouth or the stomach-pump, aided by clysters of the same, anodynes, venesection, and leeches. Should death not ensue, or the body not pass by the anus, Nature, in some rare cases, favours its escape by the formation of abscess, and art by incision through the stomach or intestine.

8. The Extraction of Foreign Bodies from the Rectum.

These have either traversed the whole intestinal canal, or originated from hardened fæces in the rectum, or entered from without.

The most appropriate instruments for their removal are bullet-forceps, polypus forceps, small lithotomy forceps, smooth blunt hooks of the breadth of the finger, and scoops with long handles. Before operating, the rectum is to be filled with gruel mixed with one fourth of olive-oil, in order to prevent its coats from getting into contact with the foreign substance, or damaged by the forceps. The patient is made to lean over the back of a chair and grasp its front edge, the buttocks being held apart by an assistant standing to the left side. The anus is then closed with the left hand, and the forceps, well oiled and shut, introduced by a gentle movement betwixt the fingers. The blades are next separated, carried upwards, and then approximated. The Surgeon will soon be sensible whether he has secured the object of his search; if not, he directs the blades upwards and downwards till he has; he then drags it out by a slight rotatory motion, as in the extraction of a stone during lithotomy. An irresistible call to stool seizes the patient, the liquid contents gush forth in a full stream, and at that moment the foreign body is evacuated. I have thus more than once taken away a mass of incrusted excrement which had been for years accumulating in the gut. I succeeded by the aid of a silver spoon in relieving an old gentleman thoroughly of an infirmity which had troubled him for a long period of time. He had previously been treated for stricture of the rectum by means of bougies, and once by dilatation through incision. He had annually resorted to Carlsbad to drink the waters, the radical evil having been overlooked. All loose stools uniformly swept by the incrusted fæces. The extracted lumps possessed a calcareous crust, and were very voluminous.

Leber failed in removing, by the forceps, a piece of wood one foot long and one inch thick; he at length bored it through, and pulled it out. Marchetti extracted a dried sow's tail by passing some membrane over it, so as to hinder the short prickly bristles from irritating the mucous lining. Von Walther drew away with forceps from the rectum of a peasant a piece of the root of a tree, which measured seven inches; Von Graefe, in like manner, the end of a stick; and myself a shoemaker's pliers from a lad.

Wherever the foreign body, either on account of its magnitude, or its being obliquely wedged in, cannot be got away without violence, it will be expedient to enlarge the orifice of the anus with a probe pointed bistoury. In order to insure a clean incision, the left index finger, smeared with oil, is to be inserted with the volar aspect towards the sacrum, as a guide for the knife, which is made to cut for about an inch in the direction of the *os coccygis*. This facilitates the extraction, and the wound readily heals under cold applications, and injections of gruel into the rectum.

9. The Extraction of Foreign Bodies from the Female Parts of Generation.

For this purpose the surgeon may commonly use his fingers or a polypus forceps; but if the foreign body be bulky and wedged in, then bullet or lithotomy forceps and broad hooks. The patient being seated upon the edge of a table, facing the light, with the thighs held widely apart by two assistants, the surgeon squirts a little oil into the vagina, examines the nature of the body with the fingers and speculum, then passes up the forceps previously oiled, gradually opens them, insinuating one blade behind the body, and finally withdraws it in the line of the pelvic axis. This is nowise difficult, when the body is not very irregular in shape, and the parts are not inflamed or swollen. Where, on the contrary, the vagina is contracted and deprived of elasticity through inflammation and puriform secretion, and the substance large, it must be broken up into fragments and taken away piece-meal.

After its removal, the vagina ought to be well syringed, and the patient put into a warm bath. Mucilaginous decoctions may be subsequently injected, and the parts fomented with infusion of chamomile and Goulard lotion.

Foreign bodies in this situation are of every variety. If allowed to remain long they determine inflammation, suppuration, and rupture of the vagina, either into the rectum or the bladder. Thus communication with these cavities and effusion of their contents into the vagina is the obvious result. Foreign bodies, if sharp and angular, occasion, now and then, dangerous lesions. I once had to remove from a young lady a number of different sized fragments of a porcelain urinal which had broken under her. The labia were severely wounded, and the vagina completely filled with the sherd. The hæmorrhage was so excessive as to have caused fainting. I extracted the whole by means of polypus forceps, and inserted a few fine sutures. The wounds healed promptly. Large, incrusted, and firmly adherent sponges were removed by me with lithotomy forceps, as also a variety of full-sized wooden pessaries, all in like manner covered with a crust. Some of these I was obliged to break, using several forceps with the aid of assistants, or else cut them in half with Liston's bone-scissors. Morand withdrew from a lady a silver pessary through the openings in which bridles had shot across, and held it fast. Dupuytren extracted from a nymphomaniac a pomatum pot; on another occasion, an old ring pessary, which was wedged in, and caused most urgent symptoms. A girl introduced the cone of a pine into the vagina. The sharp imbricated scales got lodged in the mucous membrane, and were picked out one by one after the cone had been cut in pieces. The vagina was excessively turgid.

REVIEWS.

Stricture of the Urethra, its Pathology and Treatment; comprising Observations on the Curative powers of the Potassa Fusa in that Disease, with Cases. By Robert Wade, F.R.C.S., Senior Surgeon to the Westminster General Dispensary, Fellow of the Royal Medical and Chirurgical Society, and late Lecturer on Pathological Anatomy. Second Edition. Greatly enlarged. Royal 8vo. Pp. 247. London: J. Churchill. 1849.

It is a gratifying reflection, that the inquiring spirit of the age, although at times following after visionary pursuits, and not unfrequently embracing error, yet more frequently discovers truth, extends human knowledge, and increases human happiness. The labours of scientific investigators are

every day adding to our comforts, and it may truly be observed, that during the last few years the healing art has made greater advances towards perfection than it did in quadruple the time half a century ago. Numerous affections, that were once little understood, are now treated with a success that formerly would have appeared marvellous. Diseases then abandoned to chance, or rather the unaided efforts of nature, are now brought so much within the dominion of the physician's or surgeon's power, as to be either cured or greatly mitigated. The disease, in its various forms, of which the treatise now before us professes to treat, is one of those maladies which, though less formidable than many others, produces an immensity of discomfort, and often considerable suffering; yet the surgeon's aid can, in most instances, be of great service; and we rejoice to be informed by our author that his experience and observation on strictures of the urinary passage, have led him to what he conceives still further improvements in practice. It may here be well to say, before proceeding further, that in those cases where the nitrate of silver has been used, he would recommend in preference the potassa fusa.

"The causes which chiefly tend to the production of strictures of the urethra may be conveniently placed in the order of their degree of liability to produce that disease. 1stly, Protracted gonorrhœa. 2ndly, Continued chronic urethral inflammation in persons possessing an irritable urethra. 3rdly, The continued discharge of unhealthy urine containing the lithates or phosphates in excess. 4thly, calculi or other causes producing irritation and inflammation of the kidneys, ureters, or bladder, subsequently extending to the urethra. 5thly, External or internal injuries and tumors."—P. 16.

There can be little doubt, that by far the most common cause of urethral stricture is gonorrhœa; in nineteen instances out of every twenty it is so, and especially where injections are improperly employed, and we are of opinion that this would be a comparatively rare disease, if it were not preceded by the gonorrhœal poison. How seldom stricture of the œsophagus occurs; but subject that passage to the influence of an irritant poison, and cause inflammation, then its contraction is a most probable sequel. Under the second head given by our Author, he refers to other causes giving rise to chronic inflammation, than gonorrhœa—and these he considers as primary affections, proceeding from spontaneous local irritation.

Mr. Wade describes strictures of the urethra under the following heads:—

"1. The dilatable stricture. 2. The simple chronic stricture. 3. The impassable stricture. 4. The irritable stricture. 5. The inflammatory stricture. 6. The stricture with marked disposition to contraction. 7. The spasmodic stricture. 8. The stricture from external or internal injury."—P. 18.

These pathological distinctions might, perhaps, have been advantageously reduced to a less number. The irritable stricture and the inflammatory might with propriety have been considered as degrees of the same state—as acute or subacute. The *irritable* condition, attended with *vascularity* or disposition to bleed, is, of course, but another mode of expression for a certain amount of inflammatory action. Again, stricture, with marked disposition to contraction or spasmodic stricture are, perhaps, equally reducible to one head.

"The gum elastic catheter is a most useful instrument, and often proves of very great value in the treatment of stricture. Gum catheters should be kept of their proper curve by a stilette; and they may be used with or without it as occasion may require. Steel sounds sometimes, coated with silver to preserve them from rust, unless the urethra be too irritable to bear them, are, undoubtedly, far preferable to all other instruments in dilating a stricture which often becomes so hard and contracted, that bougies of a less solid material are very inefficient, if not entirely useless. Silver catheters are also very useful, especially when an instrument of very small size only can be employed; for, being lighter than the more solid sound, they are consequently less likely to injure the urethra."—P. 35.

There are few operations in surgery requiring more than the introduction of the catheter,—it is to be acquired by practice, and practice alone. We have heard one of the most distinguished of the Profession assert, that he owed much, or all his great success in life to the fortunately speedy introduction of this instrument in a patient of high station, when one or two others previously failed. In the hands of a careful and adroit operator, the silver catheter is infinitely preferable to the elastic gum one. Where there are false passages, and it is difficult to find the natural way to the bladder, and more time is required, the gum bougie is apt to slip or move from the stilette, and at all times the sense of touch is far more perfectly transmitted through the medium of silver. We quite agree with the Author that metallic instruments are the best for dilatation.

As regards the use of caustic, Mr. Wade says:—

"Potassa fusa, when properly applied to strictures of the uretha causes a sensation of heat seldom amounting to pain, which is commonly of very short duration, although it may remain for one hour or more. When freely used, its application is often followed for a day or two, and sometimes for a week, by a slight mucous or muco-purulent discharge, occasionally tinged with blood; generally, however, if only gentle pressure be made against the stricture, there is apparently but little discharge beyond that which is observed on the point of the bougie.

"* * * The potassa fusa, when first applied to a stricture, causes an increased secretion of mucous, which, mixing with the alkali, renders its action less powerful, and, at the same time, diffuses it freely over the diseased part. *I believe that its good effects arise more from its promoting absorption of the stricture than by absolute destruction of the tissues.*

"The property possessed by the potassa fusa of combining with oily substances and animal mucus, forming a saponacious compound, renders its action more mild, and also enables it *to penetrate the hardened tissue of a stricture to soften and promote its absorption, more effectually than the nitrate of silver.* Whatever may be the precise mode of its action, the superiority of the potassa fusa to the argenti nitratis in opening a stricture I have had ample opportunities of experiencing."—P. 43.

Although we do not for a moment deny the frequent necessity of using caustics in removing morbid depositions obstructing the canal, yet, wherever it is practicable, the dilating process should be had recourse to—if only a bougie of the smallest number can be applied. Though, perhaps, a more tedious method, it is safer, and we can now call to mind cases where the stricture had been pronounced impassable, yet under the effects of opium, warm baths, &c., a small bougie or catheter had been introduced, and, by gradually increasing the size of the instrument, the passage has, in course of time, been rendered sufficiently permeable. We remember an instance, some years ago, of a patient, labouring under what the surgeon represented as impassable stricture, coming to Edinburgh from the Orkneys. A false passage had formed through the perineum, and, by that outlet, the bladder had for some time been relieved. After considerable patience, the smallest bougie was introduced, and a cure ultimately accomplished. Mr. Wade argues very rationally on the *modus operandi* of the potassa; and he has done the Profession service by bringing into notice an agent which he shows to be superior to nitrate of silver, and equally safe. In the application of potassa fusa to other parts, we agree with our author, that it has a greater power of producing absorption than the lunar caustic. The manner in which Mr. Wade applies his agent is by inserting a small portion of the potassa at the end of a soft bougie; the quantity employed is from the eighth to the sixth of a grain. "It will be rarely necessary," he says, "to exceed the sixth of a grain." It is recommended to be applied every second or third day; but, should there be scalding, irritation, or decided pain from the last application, to allow even four days to intervene.

We have perused the Treatise before us with considerable interest. It is the production of a painstaking and an accomplished surgeon; and well illustrated by cases, clearly and fairly showing that the potassa fusa is a very valuable remedy. This edition is considerably enlarged by fresh and important matter, and is a very creditable production. We have little doubt of its merits insuring it an extensive circulation.

REPLY TO MR. SKEY'S LETTER ON THE TREATMENT OF CHRONIC ULCERS WITH OPIUM.

[To the Editor of the Medical Times.]

Sir,—When I undertook to lecture medical pupils on the causes and treatment of ulcers of the leg, I considered it quite as important to caution them against what I believed to be useless or injurious, as it was to inculcate correct principles of treatment. One of the greatest difficulties with which the student has to contend, in the present day, is, to select judiciously from amongst the multitude of remedies brought before him, and it becomes a paramount duty of every teacher to assist him in separating the wheat from the chaff. In carrying out this intention, I deemed it my duty to state my opinion of Mr. Skey's method of treating ulcers by opium,—an opinion formed, partly upon actual experiment, partly upon the style of argument adopted in Mr. Skey's pamphlet, and, I must add, somewhat strengthened by the letter he has just published in your Journal.

The mainstay of the arguments in favour of the opium treatment rests upon facts; and herein it is that I think I detect its weakness. I clearly trace in my own mind throughout a striking confusion of the *post hoc* and the *propter hoc*, somewhat after this fashion:—"A poor man, with a large chronic ulcer of the leg, is taken into St. Bartholomew's Hospital; he is kept in bed; a liberal diet is given him; some mild application is used to the sore; *opium is given night and morning*, and the sore rapidly heals." Or, to take the case of Mr. P., a Governor of St. Bartholomew's Hospital, quoted in Mr. Skey's letter, whose appearance in Court is to set the question at rest for ever. It is true opium was given, but in the next paragraph it is stated, that the limb was *strapped and bandaged*, which, in my humble opinion, as also in the former case where rest and good diet were enjoined, had far more to do with the cure than the opium—*the real value of which can only be ascertained by abstaining from other acknowledged means of cure during its administration.*

The paragraph I published in my Lectures had simply for its object the exposition of my own views upon this subject; I never dreamed of changing Mr. Skey's opinion,—and, as I now learn that his work has been translated, and has diffused itself over the greater part of the civilised world, I am only surprised he has condescended to notice my humble production. Had I been previously aware of the world-wide celebrity of this opium treatment, I should, probably, have expressed myself more guardedly; there is, however, perhaps, some excuse for me in the circumstance, that, although this book has been published fourteen years, I have met with no mention of it in any Treatise on Surgery, whether British or Foreign, that has appeared since that time; and even Mr. Vincent, a former colleague, though he devotes a special section to the subject of ulcers of the leg, does not allude to the opium treatment. The only exception, that I am aware of, is in a work recently published by Mr. Chapman on Ulcers, where, on page 36, I find the following paragraph:—"In treating by this remedy alone the kind of cases indicated by Mr. Skey, I have not met with the same degree of success which attended the employment of opium in his hands." Mr. Skey states his conviction, that opium will earn more laurels than ever, in consequence of my rash and ignorant attack, and upon this he is willing to stake his professional reputation against mine. I can only say I am quite ready to accept the challenge. Let some Hospital Surgeon act as umpire; let six cases of chronic ulcers of the leg be selected as nearly resembling each other as possible, of these let each of us take three. I will confine my treatment to what I must still venture to call the principle of mechanical support, although Mr. Skey denies its physiological accuracy—no medicine shall be given, and exercise shall be allowed. Let Mr. Skey administer opium, and apply some simple dressing to the ulcers, allowing the patient to move about, and, if the result prove that he is equally successful with myself, I will publish the fullest retraction of my former statements, and will apologise in any of the medical periodicals for having denied the value of the opium treatment. I will even go a step further than this. I will allow Mr. Skey to superadd to the opium any local treatment he likes, and if his cures are more rapid than mine I will most willingly and publicly acknowledge my error.

Whatever be the result of such a trial I think the cause of truth must gain, and one or other of us will have succeeded in disabusing our minds of a certain amount of error. If this challenge is declined on the

part of Mr. Skey, there remains no alternative but that we must agree to differ, and leave those of the Profession who take sufficient interest in the subject to make experiments for themselves, and judge between us.

I remain, your obedient servant,
GEORGE CRITCHETT.

Finsbury-square, July, 1849.

THE CHOLERA AND THE PRESENT POOR-LAW MEDICAL ARRANGEMENTS.

[To the President of the Poor-law Board.]

SIR,—Are our Medical arrangements at all commensurate with the present emergency?

This is a question to be answered negatively or affirmatively, at once and speedily. The urgent remonstrances of the Committee of the Poor-law Convention must prove to you how far from satisfactory is the performance of their functions, for their salaries are meagre, insufficient, and degrading to their Professional reputation.

The thief, who is carried off in his malarious prison by cholera, has a well-paid, well-accoutred physician to attend him previous to his dissolution; a jury of his countrymen are summoned to adjudicate over his remains, lest a shadow of a neglect within the walls have taken one iota from his quantum of animal life. Within those walls you have a dispensatory, a well organised medical staff, and every appliance to alleviate human suffering. I challenge the inspection of your union workhouses, at least the majority of them, and contrast the appliances of the one with the appliances of the other.

In some you *have no medicaments* ready for the trial, which may come on at a moment's warning,—in others, not a single apparatus for generating external heat to warm the surface and stimulate the expiring functions of the skin. You have no paid and efficient nurses in your crowded establishments, whilst the inmates of prisons have at least an able-bodied wardsman to raise the head and smooth the pillow of a dying fellow-sinner. Old crones who fall asleep when the first shades of evening steal into the chambers are not the persons to tend the choleratic during the night.

The twopenny-halfpenny remuneration per case which you give, will not insure the wholesome drug, or guarantee a praiseworthy attendance from your Medical Officers.

Summon, ye coroners, a jury on every pauper who dies, and strike an average upon the number of cases the Medical man has to attend for his salary, and you will find the pauper could not do well,—a more cold, calculating piece of injustice never having crept into the annals of administrative law. The intention of the Legislature to provide proper attendance upon the poor has been *subverted*, the recommendations of the Poor-law Commissioners themselves have been *perverted*, and a sanction has been obtained to the letting of districts at a sum which common sense points out as inadequate to every right-minded, right-thinking Guardian or Commissioner.

Come what may, we must for a season submit to the exigencies of our position, and do our utmost to alleviate the sufferings of those afflicted with cholera; but if the poor are well attended, it is at our own cost, not that of the public who have taken advantage of our competition with one another to plant a deadly thorn upon the back of the deserving pauper.

If the negative of the question first proposed in this letter has been proved, it behoves you, Sir, to organise your Medical staff and pay them honestly. Wherever there is disease, there is also filth. Give powers to your officers to insist upon its immediate removal; make them real officers of health. In every Union workhouse fit up a proper dispensatory, and supply it at the cost of the Union with every necessary. Do not throw the charge of the drugs, and bottles, and ointments, and poultices, as now, upon the ill-paid Medical officers. Place at their disposal every implement which the prison contains to sustain the powers of a sinking frame, and let not the reproach remain that criminals *may live*, but the pauper *dies*.

This pen may write too boldly and too freely, but it writes in sincerity.

On the verge of an impending danger, let the public feel the abhorrent contrast between the Medical relief in prisons compared with that of Unions. Where one hundred prisoners, (for these are facts,) are attended for a sum, one thousand paupers are attended for the same. When a body of infantry, in all the vigour and strength of manhood, have three Surgeons to attend them in sickness, and at a cost of 500*l*. per annum, and every drug provided, it is a scandal to find, that the Commissioners have sanctioned the appointment of Surgeons to districts in which there are 8,000 or 10,000 ill-fed, ill-clad paupers liable to every possible complaint from innate poverty, for sums varying from 30*l*. to 50*l*.; and the poor doctor finds horses and drugs out of this degrading recompense, if recompense it can be called.

Now, Sir, is the time to consider what is to be done. You may say the rates will not bear augmentation, and you abhor a call upon the Consolidated Fund; so do I. Charge the Medical relief wholly upon the Unions; stay the cost of removals; and lessen the legal expenses; and apply the sum saved to the alleviation of suffering, and the provision against the invasion of epidemics. Pay so much per head on the relief list; pay by distance how you will, provided only you prevent the decimation of the pauper population by a good and wholesome system of Medical relief—a system less riddled by time, more able to resist the attack of foes so destructive as cholera and typhus.

I remain, Sir, your obedient servant,
ALFRED EBSWORTH.

MEDICAL WITNESSES IN CRIMINAL PROSECUTIONS.

[To the Editor of the Medical Times.]

Dr. Letheby's Second Lecture on the Chemistry of Poisons, reported in the *Medical Times* of July 14th, 1849, he speaks of some of the circumstances which tend to increase the crime of secret poisoning, amongst which he enumerates, "a want of watchfulness on the part of medical practitioners," the "gross negligence of many of our county coroners," and "the indisposition of judges and juries to convict." To medical practitioners are attributed carelessness, ignorance, or indisposition to be engaged in a criminal prosecution. Passing over the two former, I think it may be shown that medical men have little inducement, voluntarily, to engage in investigations likely to lead to criminal prosecutions. Their treatment by Coroners since the passing of the Act of Parliament entitling them to remuneration for giving evidence, has been every way calculated to cause reluctance in entering upon such service. Medical men are considered the servants of the public, but there is a duty also which they owe to themselves. Formerly, their evidence was taken in almost every instance of violent or sudden death, and they made the necessary investigations, with the almost certain prospect of being required to attend the Inquest. It is not so now. Since the Act of Parliament provided for their pecuniary remuneration, their evidence is seldom taken on ordinary occasions. Medical men may be called in by the friends of the deceased, or by officious neighbours. They may, if they please, investigate the causes of death, and prepare themselves to give evidence; they may even be officially informed of the time of the inquest, and warned to hold themselves in readiness to be called upon; and, after all this loss of time, and perhaps considerable research, they will not unfrequently find that the inquest has taken place, and their evidence been dispensed with. This is the experience of the Profession in most parts of the Kingdom; it is part of the working of the Act, and is little calculated to encourage the watchfulness which is represented as their duty. If they do manifest indisposition to be engaged in a criminal prosecution, is there not sufficient cause? Their time must be of very little value if it is not a serious loss to be so engaged. The remuneration to which they are legally entitled is in no degree commensurate with the inconvenience, anxiety, and responsibility. Besides this, in the present state of our penal laws, it must be contrary to all their best feelings to take any part in proceedings that may result in subjecting an immortal being to a premature death.

The next circumstance to which the lecturer attributes the increase of poisoning, is the gross negligence manifested by many of our county coroners, the usual character of "Crowner's quests," and the indefinite form of their verdicts, of which he speaks in terms of great contempt. It is, indeed, impossible that such investigations can be satisfactorily conducted without the superintendence of a conscientious and enlightened coroner, a respectable and intelligent jury, and the best evidence that can be obtained. Many inquests have not the advantage of such a coroner, and too often the juries are, in part at least, composed of men wholly incompetent to take a clear and enlightened view of a difficult case, or to understand the nature and value of evidence.

Lastly, I shall notice "the indisposition" which, the lecturer says, "exists on the part both of judges and juries to convict" Is not this indisposition to convict honourable to them? It can scarcely be supposed to arise from any other cause than that previously alluded to as affecting Medical men, the state of our criminal code. If there was a scale of punishments in some degree proportioned to the atrocity of the offence, leaning rather to the side of mercy than of cruelty; and if that scale contained no punishment which was inconsistent with justice, sound policy, and the principles and precepts of Christianity, fewer persons would feel such reluctance to prosecute, to give evidence, or to pronounce a verdict of guilty. So long as the punishment of death is recognised in our law, there will be difficulty in convicting criminals. Let punishments be rendered consistent with the benign principles and precepts of the religion of which this country makes such high profession, and the law will probably be not only easier to administer, but prove more efficacious for the prevention of atrocious crimes.

JOHN FOTHERGILL, M.R.C.S.

A WORD ABOUT CHOLERA.

"Our hospitals should be the altars of science, where her lamp should be kept constantly burning:—there is plenty of oil, if there were but zealous priests to tend the flame."—*Ross's Lectures on Asiatic Cholera.*

In offering a few observations on cholera, I am nowise affected with an overweening presumption. I feel merely a laudable anxiety to court inquiry and discussion, and to elicit opinions which, when I find them the most rational, I at once most freely and most readily espouse. I am one of those, Sir, who think that there is *always* something to be acquired in our Profession; and I am one of those who seek every opportunity to search after and to acquire it. With this short apology I wish to propose a few questions.

Can the respiratory function of our "third lung," the skin, as well as that of the true lungs, be so far affected as to occasion cholera? We know that the capillary circulation throughout the cutaneous surface in that disease is remarkably feeble:—heat is driven from without inwards, and there is an arrest of the usual exhalation (insensible perspiration.) We also know, that in this disease, oppression at the chest—a sense of sinking—a collapse of respiration as it were, are very remarkable. Now, the chief difficulty seems to be, what is it which interferes with these functions? It seems to me, that after all the theories broached upon the matter, "the defection in atmospheric electricity," as stated in France by M. Maussam, or "the subtraction of *animal* electricity," as maintained by M. De Chavagneux, are the most probable. And here, *par parenthese*, I deem it necessary to observe, that I do not hold with the French school, nor with the Wilson Philips of the English, the very materialist doctrine that nervous influence and animal electricity are *quid unum et idem*. Dr. Tring, in his "Principles of Pathology," has ably refuted that hypothesis. It has been widely believed, that animal electricity is merely a function intended to exercise determinate results, and that it has an inseparable and correlative connexion with that vital power wherewith the Creator has endowed animals,—the nature of which vital power we do not and cannot know, we do not and cannot understand. It has been also believed, that the "ganglia of the great sympathetic may be viewed as the system of organic life,—the vital system of nerves whose centre is the semilunar ganglion;"(a) or, in other words, a system which is made instrumental in distributing that electric influence for the due exercise and maintenance of the several organic functions. One of these functions (the principal one) is respiration. Now, let us ask, is atmospheric air so modified by a deficiency of electricity, or is the abstraction of animal electricity so powerful as to hinder or disturb this function—the pulmonary and cutaneous capillaries losing their accustomed stimulus from the ganglionic system—and this system losing its accustomed instrumentality in supplying it? Again, whereas, "1st. the blood of the vena cava, superior and inferior, is drawn *towards the heart* during *inspiration*. 2nd. The blood is driven *towards the viscera* in the same *veins* during *expiration*. 3rd. The *arterial* blood is also driven towards the viscera *during expiration*." Let us ask, does the amount of *expirations* as to intensity and duration exceed that of *inspirations* in cholera? If so (and I think it can be maintained) that would account for the fact of the intestinal canal performing a function vicarious to that of the lungs, as in phthisis, but much more sustained as to quantity, and more anomalous and *sui generis* as to quality. Again, is the absent instrumentality on the

part of the ganglionic branches, which influence the *cutaneous* capillaries in *their* respiratory functions, to be found exercising a vicarious function in like manner in the intestinal canal? Now, as there is something given off in healthy respiration (pulmonary and cutaneous) which is bad, and something in exchange required which is known to be good; so, in the respiration of cholera (pulmonary and cutaneous), that which should be given off is not given off, or very imperfectly given off, and that which should be acquired is not acquired, or very imperfectly acquired. There is, then, an anomalous excitement in the capillary circulation of the intestinal canal—a sort of fever of the blood—a sort of *muco-enteritic* "sweating sickness," if I may be allowed the expression, whereby the blood is deprived of its water, and with the water of the salts which sustain its fluidity. All the secretions are altered, and arrested, and deprived of their salts and their acids. A deoxygenating process appears to be carried on, and this more particularly in that chemico-vital laboratory, the stomach, than elsewhere; for, here there is always a "burning" sensation complained of, in this disease, the evolution of heat, mayhap, from the combustion of hydrogen in the production of water. The salts of soda and potash from the bile, saliva, &c., &c., thus lose their oxygen. The acetic acid of the gastric juice loses it share too, while the hydro-chloric acid of the gastric juice gives off its hydrogen, and the free chlorine unites with the sodium and potassium to form chlorides which are eliminated in the rice-water, vomiting, and purging. The carbon is in excess in the blood in the shape of urea It may exist also in the carburetted hydrogen in the large intestines, and perhaps in the small intestines.

If a deoxygenating process, then, be the result of defective electricity, (or, for this is hypothesis, the result of *any other yet to be ascertained cause,*) to oxygenate the blood would appear to be the most rational mode of treating cholera. Dr. Stevens' system is entirely calculated to effect this object. The vehicle of the salts he employs is spring water, which in itself contains, besides its salts of soda and magnesia, atmospheric air. This vehicle he largely exhibits, thus decarbonising the blood at the same time that he restores to it its lost salts. Then the external aids of friction, heat, embrocations, &c., are, meanwhile, in active operation. The capillary circulation in the skin is excited, which was previously passive and quiescent—heat is restored—respiration becomes easier—health is finally established. So fully was I possessed of the idea that Dr. Stevens' was the only rational mode of treating cholera, that I determined on testing it when the disease afflicted this locality, and with the happiest results. Albeit unhonoured by an hospital appointment, and with locks unsilvered as yet, nevertheless, some six or eight private cases fell to my lot, and the termination of these cases convinces me that, under God's providence, the saline system deserves all the merit Dr. Turley ascribes to it.

Your very obedient Servant,

JAMES JOSEPH COPPINGER, M.D.

Cove of Cork, July 10, 1849.

MEDICAL NEWS.

APOTHECARIES' HA —Names of gentlemen who passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday July 19th, 1849.—Frederick Thomas Barkway, Gravesend; Charles Octavius Rowley, Barnsley; Henry Duncan Smith, Sandwich, Kent; Benjamin Tillyer Blunt Baillie, Dorchester place, New North-road; William Squire, Silsoe, Beds; William Tomlin, Nottingham; William Thompson, Drigg, Cumberland; John Hayes, Langton, Staffordshire; William Thomas Sampson Ingram, Hardy, Devonport.

ROYAL COLLEGE OF SURGEONS.—The following gentlemen, having undergone the necessary examinations for the diploma, were admitted members of the College at the meeting of the Court of Examiners, on the 20th inst.:—Messrs. James Goodchild Wakley, Harefield, Middlesex, (son of the hon. Member); Louis Joseph Mauran, London; Frederick Fallows, Belfast; Theobold Ringer, Laugharne, Carmarthenshire; Alexander George Cockburn Thiselton, York; Henry Saunders Grant, Northampton; Robert Powell, Bristol; Harvey William Dixon, Putney; David Grant M'Pherson, Bristol; John Wilcocks Waken, London; Henry Newcombe, York; Charles Terry, Bath; and Joseph Powell Swanwick, Prestbury, Cheshire.—The following gentlemen were admitted on the 23rd instant:—Messrs. Samuel Atkinson Brough, Marlborough, Wiltshire; Robert Rook Prance, Hampstead; Charles Dering Nettleton Devonport; George Whitaker Walter, Market Rasen, Lincolnshire; George Thomas Jones, London; William Helps, Gloucester; Francis Harrison Walmsley, Manchester; William Walkinshaw M'Creight, Castle Wellan, County Down; Thomas Middleton Williams, Sherrington, Buckinghamshire; and Patrick James Mullarky, Sligo.

OBITUARY.—On the 18th inst., at Camberwell of Asiatic cholera, Robert Young, Esq., M.D. aged 47, third son of the late Vice-Admiral William Young.—On the 18th inst., at Portsmouth, after a few days' illness, W. Birrill, Esq., M.D., Surgeon to the Forces, H.P., aged 56.—At Stockton, on Wednesday week, Mr. Henry Milburn, Surgeon.

THE HUNTERIAN ORATION.—It is understood that Mr. F. C. Skey, of St. Bartholomew's Hospital, will deliver the annual oration in memory of John Hunter.

THE GENERAL BOARD OF HEALTH, at a full Board, received the President of the Academy of Medicine in France, M. Majendie, on a mission of inquiry from the French Government as to the progress and treatment of cholera in England. M. Majendie was accompanied by Dr. M'Laughlen. Professor Owen and Mr. Hodgson, of the College of Surgeons, were present at the conference.

THE CHOLERA.—This disease has, during the past week, been making fatal progress in the provinces and in the metropolis. In Liverpool and Manchester the deaths have been greatly augmented, and it has extended its ravages to villages, which, at its former visitation to this country in 1831, entirely escaped. It has been found, in most instances, that, wherever cholera cases have occurred, there has been a neglect of those measures which experience has proved to conduce greatly to the salubrity of towns and villages. Indeed, the latter require sanitary reform as much as our great cities. The dwellings of the rural labouring population are generally built without any regard to the health of the inhabitants—rarely being furnished with drains, and exposed on all sides to influences which act prejudicially to health. Hence, there is scarcely a village in this kingdom where typhus is not constantly located, and where it occasionally breaks forth with all the virulence of a plague. We subjoin the Registrar-General's report of the health of London during the past week. The deaths from all causes, which in the two previous weeks were 1,070 and 1,369, rose in the last to 1,741; a number which exceeds the average of the season by 733. In the two previous weeks the deaths caused by cholera were 152 and 339; but in the last they have reached 678, whilst the weekly average is only 8. Of the 678 persons who have sunk under the epidemic, 355 were males and 323 females, a more equal distribution than in previous weeks; the rate of increase is apparent in the fact, that in each of the last two weeks the mortality from cholera has been about double that of the week immediately preceding. The mortality from diarrhœa and dysentery also increases, the deaths in three weeks having been 51,100, and 146; while the weekly average of the season is not more than 84. The whole mortality from the three diseases, in last week, is therefore 824, and gives an excess on the average of 732, which almost exactly coincides with the excess of mortality from all causes, as stated above. The diarrhœa was fatal in a large proportion of cases, to children under two years of age. The increase of cholera is observed in each of the five metropolitan divisions, except the northern, which comprises Marylebone, Pancras, Islington, Hackney, and Hampstead; where the deaths in the week were only seven. But it is chiefly remarkable on the south side of the river, where the deaths in the last three weeks were successively 93, 192, and 443. In Newington they were 53; in St. George, Southwark, 51; in Bermondsey, 61; in Lambeth, 106. In Rotherhithe the deaths were 37, the same as in the previous week. Typhus continues near the average; whooping cough above, scarlatina and small pox considerably under it. Two persons died of privation; three of intemperance.

The mean reading of the barometer in the week was 29·692, and lower than in the previous week. The mean temperature was lower than the average, except on Monday and Tuesday. The highest occurred on the former day, and was 83·6. The mean of the week was 60·5, less by 6 degrees than in the previous week.

THE COOPER TESTIMONIAL.—We hear with great regret, that the subscriptions for a testimonial to record the esteem in which the late Professor Cooper was universally held for his honourable character and private worth, have only amounted to 120*l.*, a sum quite inadequate even for a painting or bust of the deceased, whose distinguished acquirements and ability as a teacher, as well as his invaluable services in the improvement and diffusion of surgical science, entitle his memory to be recorded either in a scholarship or prize.

MUNIFICENT GIFT TO THE UNIVERSITY OF OXFORD.—A truly splendid donation of an entomological collection, said to be one of the richest in existence, and of a valuable library on the natural and physical sciences, has just been made to the University by the Rev. W. F. Hope, M.A., of Christ Church, with the twofold object of enriching the new museum, and of assisting the University in the efforts about to be made for the more effectual encouragement of scientific studies. The whole collection of insects and books is said to be worth 10,000*l.*

THE PHARMACEUTICAL SCHOOL DINNER.—This dinner took place at the London Tavern, on Tuesday, the 17th of July, Dr. Copeland, F.R.S., in the chair. It appeared to give general satisfaction, and was numerously attended. The Chairman, in proposing "The Pharmaceutical Society," said, that the Society had already been instrumental in raising the qualification of Pharmaceutical Chemists, diffusing information among the members, and drawing attention generally to chemical science. When the objects of the Society were fully realized, as he trusted they would be ere long, one great source of anxiety would be removed from that branch of the Profession to which he belonged, namely, uncertainty in regard to the preparation of medicines. He congratulated the members on the acquirement of a Royal Charter of Incorporation, and trusted that, by a persevering application of the influence they possessed with Members of Parliament, an Act would be obtained, obliging all persons to pass an examination before commencing business as Pharmaceutical Chemists, and thus affording to the public a guarantee of their qualification. In the School of the Society, Professors of the highest eminence were appointed to deliver lectures on Chemistry, Materia Medica, Pharmacy, and Botany. There was also a laboratory for practical instruction and research, an extensive library, and a valuable and interesting museum. This School had already met with an amount of success which had been a source of surprise and satisfaction to the Medical Profession, considering that it was hitherto entirely a voluntary Institution.—[We sincerely rejoice in the success of the Pharmaceutical Society, believing that it will eventually be the means of raising the status and education of the great body of chemists and druggists in this country. We regret, however, to be compelled to say, that we do not think the Society has taken those energetic measures which it ought, to repress "counter practice." There has certainly been recorded an opinion against it; but this is not enough. So respectable a body of men as the Officers of the Pharmaceutical Society should sternly set their faces against a system which experience has proved to be fraught with many evils. The circumstance that there are some medical men who "compound physicians' prescriptions" should not induce the Society to neglect an imperative duty. A dispensing surgeon is not in danger of committing the serious errors of a prescribing druggist; hence the Society should use its influence to repress a system which, while it may be a source of pecuniary advantage to its members, adds nothing to their respectability.—ED. *Medical Times.*]

The Medical Directory.—We are authorised to state, that the proprietor of the "Medical Directory" has transferred the entire management of that work, in its editorial as well as publishing departments, to Mr. Churchill, in whose hands, we have no doubt, many of the difficulties which have militated against the getting up of the work correctly, will vanish. The value of such an index to the Profession is indisputable; its correctness is all that is required. Let, therefore, each member of the Profession contribute his quota of information, when called upon to do so by the annual circular, which, we suppose, will shortly be addressed to him, and the latter desideratum will be effectually attained.

Sweating Sickness in France.—In the department of the Marne the inhabitants are not only suffering from cholera, but also from a form of sweating sickness, unattended, however, with danger. It is characterized by excessive perspirations, no eruptions, except in a few rare cases. It generally lasts three days, convalescence setting in on the fourth day. The only danger attending this malady follows, it would seem, on a too early administration of solid food—the least indigestion appearing to transfer the flux from the skin to the intestinal canal, and so to induce cholera, which may then prove fatal in twenty four hours.

Highland Agricultural Society.—A general meeting of this Society was held at Edinburgh on the 11th inst., at which an interesting address was delivered by Mr. Finnie, of Swanston, on the advantages of Chemistry in Agriculture. The speaker, in the course of his address, lamented that farmers appear so sceptical, as to the benefits to be derived from the application of science to agriculture; and he cited many instances to show that the greatest advantages have resulted from the use of chemistry in analysing manures, and adapting them to various soils. We are not surprised that the farmers in Scotland appear to think little of the application of science to agriculture. Most of their brethren in England have fallen into the same error. We attribute this to the statements which some few years ago were diligently put forth, as to what artificial manures and the analysis of soils would do for the farmer. He has, to a certain extent, been disappointed; and hence he his disposed to trust alone to the experience of the past, rather than to commit himself to the guidance of science for the future. Agriculture, we conceive to be somewhat like medicine; it requires the combined aid of science and experience to bring it to the highest state of perfection.

Blistering Collodion.—A substitute for the ordinary blistering plaster has just been introduced in Paris. It consists of a mixture of collodion with cantharides, and is prepared by digesting the cantharides in ether, the latter being afterwards mixed with gun cotton. The part to be blistered is painted over with the prepared collodion by a camel's-hair pencil.

Poisoned Water.—It is not generally known to the public that the carbonic acid, or fixed air, in water, decomposes lead pipes, and thereby imparts poisonous properties to the water. Within the past few months, Sir Raymond Jarvis, of Ventnor, had occasion to repair the pipes which supplied his mansion, when, to his amazement, it was found that the large leaden feeding-pipe was almost entirely eaten away by the water, and the interior covered with a white and poisonous crust. Sir Raymond has had the whole replaced with gutta percha tubing, which, from its extraordinary alkali and acid-proof qualities, will preserve the water perfectly pure. It seems remarkable that, at the moment when our sanitary movements have commenced with so much vigour, gutta percha should have come to our aid, not only as a means of preserving the feet from damp and wet, but also as a medium for supplying us with the best of liquids, water, untainted by the deleterious properties which we have endured by the use of leaden pipes.—*The Patent Journal.*

Death of Mr. Drouet.—This individual, who acquired an unenviable degree of notoriety in connexion with the Tooting affair, expired last week at Margate, of disease of the heart.

MORTALITY TABLE,

(Metropolis.)

For the Week ending Saturday, July 21, 1849.

Causes of Death.	Total.	Average of Five Summers.
All Causes	1741	1008
Specified Causes	1737	1005
Zymotic (or Epidemic, Endemic, and Contagious) Diseases	1002	302
Sporadic Diseases:		
Dropsy, Cancer and other Diseases of uncertain or variable seat	39	41
Tubercular Diseases	206	190
Diseases of the brain, Spinal Marrow, Nerves, and Senses	117	119
Diseases of the Heart and Blood vessels	36	29
Diseases of the Lungs, and of the other Organs of Respiration	87	81
Diseases of the Stomach, Liver, and other Organs of Digestion	67	76
Diseases of the Kidneys, &c	...	...

TO CORRESPONDENTS.

"Etiquette, Ongar."—In conformity with the rules of professional etiquette.

"Juvenis" says:—"In some experiments I was making with the electro magnetic coil, a short time ago, I accidentally found that the nail was a non-conductor of the electro magnetic current; and as I had never noticed that it was a non-conductor of electricity produced by the common machine, I held my nail to the prime conductor, which received the sparks as readily as any other part of my hand. I then tried the same thing with a jar, placing my nail on the ball communicating with the inside of the jar, and found it a perfect conductor. Will you, or some of your Correspondents, be kind enough to inform me the reason that it should be a conductor of one and a non-conductor of the other fluid, as I do not recollect having seen any other substance named as possessing similar conducting powers?"

"Dr. Lees, Ashton-under Lyne," in answer to "M.D. and Chirurgus," on the value of University Degrees, remarks: "I maintain that a fair and strict examination (after a proper routine of education and diligent study on the part of the candidate,) is the best test of professional ability; but 'examination alone' is 'not the only true test of qualification.' Your pages frequently contain advertisements from gentlemen ready, for a small consideration, to polish the bluntest intellect up to the 'sharpness' of London, St. Andrew's, or any other professors; consequently, the dissipated, indolent, or ignorant student, being crammed with his medical catechism, probably passes his examination with greater facility than the intelligent plodding student, whose wasted form and hectic cheek tell how zealously he has trodden the true path to future eminence."

"Medicus" complains that "M.D. and Chirurgus" is ignorant of the subject on which he writes. While he asserts that the different Scotch Universities undersell each other, the fact is, the price of the diploma is the same, £25. St. Andrew's is £3 more than the Edinburgh diploma. That of the Faculty of Physicians and Surgeons of Glasgow is only £7 7s.; and the degree of Magister Chirurgiæ, £10 10s. At Marischal College, Aberdeen, the diploma is only £10 10s., and many obtain it without residence or Latin examination. Our Correspondent asserts, that so far from St. Andrew's being afraid to reject candidates, it does more than Edinburgh. We think, with "Medicus," that, instead of quarrelling about the price and value of parchment, we should endeavour to make our medical examinations and institutions a credit and benefit to our common country.

"Mr. Wm. Gilbert, Kingsland road."—Communication received.

"A Subscriber, Halifax."—We are sorry to see such a circular as that forwarded to us. A more tradesman-like card could not be issued. The gentleman who issued it proposes attending midwifery cases for 7s. 6d., and to give advice and medicine to adults for 1s., and to children for 6d. Cheap physic is not always the best, and we hope the Halifax surgeons, for the honour of their Profession, will set their faces against a system adopted by the firm, "who, from their experience in the Profession and attention to business, hope to merit a share of public favour."

"Mr A. Palmer, Newcastle, County of Limerick," suggests the following remedies for Cholera, which, he says, he has employed with great success:—"Pills composed as underneath are to be given one every two hours, from the time the first attack of looseness in the bowels or vomiting appears; in the early stage I have seldom failed to check it by these, and even in a very far advanced stage have arrested the disease. Cold water the only drink, and this *ad libitum*.—℞ Acet. plumbi gr. ij., opii. gr. ss., camphoræ gr. ij.: m. ft. pilula, of course for an adult. I am aware that acet. plumbi and opium have been recommended by Dr. Graves, of Dublin, but I have nowhere seen camphor recommended or tried (except in "Ponsonby's Drops.")

"R. Aiton, Staffordshire."—1. The leaves of the belladonna must be dried. 2. The work referred to is a useful one.

"J. J. W., Lynn, Norfolk."—It is necessary to give only about a week's notice to the beadle of the Apothecaries' Company prior to examination. There are, however, many preliminary circumstances to be attended to in reference to the registration of certificates. Our Correspondent had better address a letter to the Secretary of the Company, who will give him all the information he needs.

"A Country Subscriber."—A description of the Varicocele Ring, invented by Mr. Wormald, was published some years ago in the "Medical Gazette." The number we cannot name.

"Dr. Mahood, Kingstown," has found that the most excellent vehicle for taking Cod Liver Oil is in new milk, and that the disagreeable flavour of the drug can easily be covered by the addition of one drachm of oil of orange-peel to every 8 ounces of the oil; he has found this, without any exception, the best form of giving it, in his own practice and that of others.

"Mr. Salter, Poole."—Communication shall appear next week.

Answers to a large number of Correspondents we must postpone to next week.

ORIGINAL LECTURES.

HUNTERIAN LECTURES
ON THE
GENERATION AND DEVELOPMENT OF THE INVERTEBRATED ANIMALS.

By RICHARD OWEN, F.R.S.,
Hunterian Professor and Curator of the Museum of Royal College of Surgeons, Corresponding Member of the Institute of France, &c.

[Reported expressly for the "Medical Times," and revised by the Lecturer.]

LECTURE X.*

GENERATION OF ANELLATA.—Characters of the Class and of its primary divisions.—Spontaneous fission of Nais and of young Nereids.—Androgynous generative system of the Leech and Earth-worm. Diœcious arrangement of the numerous but simple testes and ovaria in Tube-worms and Nereids.—Ova, cocoons, and metabolian development of the Leech and Earth-worm.—Development and metamorphoses of Nereids and Tube-worms.

MR. PRESIDENT AND GENTLEMEN,—From the low organised intestinal worms we pass now to the consideration of the generative economy of worms of a higher organisation, of those commonly called leeches, earth-worms, sand-worms, and tube-worms, nereids or sea-centipedes, aphroditæ or sea-mice, &c., constituting a very extensive, widely distributed, and varied class; but all vermiform, and all with the body partially divided into segments like little rings, whence the name *Annulata* or Annelides, which has been given to the class, and is now generally received; they are the "Red blooded worms" of Cuvier. The Entozoa, subsisting on the chyle or other living juices of higher animals, had a nutritive system which sometimes resembled in form and structure a ramified vascular system, but usually combined the digestive, chylific, and sanguiferous functions, and always contained a whitish, colourless fluid. In the Annulata we always find a distinct system of arteries and veins, aided by a propulsatory organ or organs. The Entozoa, being in contact with the vascular tissues of the higher animals which they infest, have no need of special respiratory organs; but in the Annellata these organs are always present, though in various grades of development, and diversely modified in structure: though always composed of vascular portions of the integument. In the leech and earth-worm, the vascular processes of the delicate integument are folded inwards, and constitute small respiratory sacs like rudimental lungs, opening by lateral spiracula: in the majority of the class, the processes of the integument are pulled outwards, and commonly ramified or tufted; sometimes radiating from the head, sometimes from the dorso-lateral parts of the body-segments, and commonly of a bright red or coral colour. With this state of the circulating and respiratory system, the locomotive powers of the annulated worms are proportionally developed. In most members of the class, special locomotive organs project from the sides of the segments, in the form of short tubular processes of the integument, forming sheaths for a bundle of protractile and retractile bristles. The nervous system keeps pace with the development of the muscular system, whose actions it directs; and we now find a regular and symmetrical series of aggregated nodules of nervous matter or ganglions; and with this grade of the nervous system we find a supra-œsophageal ganglion or brain receiving sensations from rudimental eye-specks, and also from exploring processes of the integument of the head, analogous to the antennæ of insects. And here is an instructive exemplification of the law of vegetative repetition, in this first introduction of antennæ into the animal kingdom: they are not only present in two or more pairs on the head, but in some annelides are developed from the segments of the trunk, and, though similar in structure to the cephalic ones, are not called "antennæ," only because they are not situated on the head. In insects where the antennæ are fully perfected, they are reduced in number to two.

The Annellata are divided into four groups, according to easily recognised characters:—

1. The *Suctoria*, or Leeches, in which the locomotive organs are in the form of prehensile discs, or suckers.

2. The *Terricola*, with short hooks of bristles for locomotion, but without external branchiæ.

3. The *Errantia*, having tubular setigerous feet for swimming or creeping, and also external branchiæ, from the position of which the order is also called "dorsibranchiata."

4. The *Tubicola*, in which the body being concealed in a commonly artificial tube, the branchiæ are confined to the head, which is adorned with a crown of beautifully-coloured radiating tentacula.

On the first appearance of the embryo annellide, it usually appears to consist of a single segment, which is chiefly occupied by a large mass of unmetamorphosed germ-cells. And these are not used up, as in higher animals, in developing the tissues and organs of an undivided or individual whole; but, after a comparatively slight growth and change of the primary segment, proceed to form a second and a third segment, of somewhat simpler structure, and go on repeating these, in a linear series, perhaps, more than a hundred times. So that we may have a seeming individual annellide consisting of many hundred segments, in which a single segment would give all the characteristic organisation of such individual, except some slight additions or modifications characterising the first and last of the series. Thus the annellides are more simple in their structure than they appear at first sight, especially before arriving at full maturity, when in certain species, as the leech and earth-worm, particular segments are distinguished by the development therein of the special male and female generative organs. With this characteristic mode of growth, by repetition of segments, we should be prepared to expect in these creatures great powers of repair after injuries and mutilations—powers which have been made the subject of many and ingenious experiments. In the works of Spalanzani and Bonnet, more particularly, you will find recorded the most striking results of such experiments. A worm cut in two was found to reproduce the tail at the cut extremity of the cephalic half, and to form a head upon the caudal moiety. Bonnet progressively increased the number of sections in healthy individuals of a small worm, the *lumbricus variegatus*; and when one of these had been so divided into twenty six parts, almost all of them reproduced the head and tail, and became so many distinct individuals. Sir John G. Dalyell has succeeded in artificially propagating a *Sabella*, or sand worm, in the same way. The small fresh-water Naids show great powers of repair and reproduction; these little worms have a paler colour of the blood, which in most Annellata is of a bright crimson colour; but through the transparent skin of these Naids you may clearly see the circulation of the blood. There are some species found in sand or mud, such as those that stain of a red colour extensive tracts of the Thames mud at low water; which, when submerged, habitually protrude the anterior half of their body, which is remarkable for its regular oscillating movement. Bonnet cut off the head of one of the Naids of this genus, which was soon reproduced; and, when perfect, he repeated the act; and again as often as the head was reproduced. After the eighth decapitation the unhappy subject was released by death; the execution took effect, the rear ductive virtue had been worn out. This series of experiments occupied the Genevese philosopher two summer months. With this power of reproduction of lost extremities is associated that of spontaneous propagation by developing and detaching new series of segments.

Spontaneous fission has now been observed to take place in almost every order of Annellata; and, in all, it takes place at nearly the same part, near the beginning of the posterior third part of the body; but, the formation of the new annellide is due to a process of gemmation of new segments, which proceeds from the last or penultimate joint. It is most common, or has been oftenest witnessed, in the little abranchial fresh water Naides. But, Otho Frederic Müller has represented a young Syllis (his *Nereis prolifera*) in the act, in his great work, the "Zoologia Danica." Gruithuisen has described the process in a *Chætogaster*, Oersted in an *Eolosoma*, M. Edwards in a *Myrianes* (Nereis), and Schmidt in a tubicolar Annelide, called *Filograna Schleideni*.

The place where the process of forming the new segments is to be carried on is soon indicated by a slight swelling and increased vascular action. If the head or anterior segment of the species be characterized by eye-specks, antennæ, a proboscis, or branchiæ, these are developed in a certain and always recognizable degree, before the final separation takes place. In the *Myrianes*, the coloured eyes indicate the young fry. In the cephalo-branchiate annellide the gills are shown, in the stage of fission represented by Professor Schmidt, as four pairs of articulated filamentary vascular processes. In the *Nais proboscidia* the characteristic proboscis shoots out from the nascent head of the young worm, which is thus duly armed before it is cast off to provide its own nutriment. The last joint of the young Naid is specially ciliated, like that of the mother; and the corresponding portion of the alimentary canal, has thick walls with numerous filamentary or vascular appendages. This gemmiparous segment resumes its procreative function in the parent as soon as the lineaments of the head of the first young Nais are established; and a second young Nais, with a rudimental proboscis, intervenes between the first and the original parent: sometimes even a third Nais is indicated by the elongation, swelling, and active vascularity of the last joint; and thus four generations of Naids may be seen organically connected, and constituting one compound individual. The compound individual is due to the succession of incomplete gemmations: the reproductive process is completed, and the compound is resolved into the single individuals, by spontaneous fission. The nucleated cells that are aggregated in the penultimate or proligerous segment form a significant feature in its organization. As long as the Annelides propagate by this primitive mode, they manifest no ovaria or testes. These are developed in those individuals which are propagated by gemmation and spontaneous fission, when the proper season for oviparous generation has arrived. M. Edwards observed, that a Nereis allied to *Myrianes* generated in succession six young from the same posterior segment, each of which developed the true generative organs, without the parent itself showing any trace of them. M. Quatrefages has noticed the same fact in a species of *Syllis*.

In many of the Annellides, therefore, the phenomena of Parthenogenesis are manifested in the immature state; and, since the individuals so propagated alone acquire the generative organs, an alternation of generations may here be affirmed of such species: the oviparous individuals producing eggs from which the gemmiparous individuals come, and these, in their turn, reproducing the oviparous individuals.

I next proceed to point out the chief modifications of the generative organs properly so called. And first, as to the generative organs of the leech. In the medicinal species (*Hirudo* or *Sanguisuga medicinalis*) may be seen a number of pairs of little grey rounded bodies, usually nine pairs, which are the testes. A little duct proceeds from each to a common longitudinal "vas deferens," which communicates near the anterior fourth of the leech with a small pyriform prostatic gland, from which is prolonged a filiform intromittent organ, which projects from the ventral surface of the twenty-fourth ring. But the leech is androgynous, and the female organs are situated behind this prostate and penis, between the seventh and eighth abdominal ganglia: they consist of two subspherical ovaria, two short oviducts, which unite to form a single oviduct that expands into a pyriform muscular uterus. The vagina opens upon the twenty-ninth segment. In the Naids the orifices of the male and female organs are in two pairs, situated about the anterior third of the body. In the *Nais proboscidia* the ovarium is included by the substance of the testis. Two cæca extend inwards, at the breeding season, from the two anterior generative pores, which are then found filled with spermatozoa grouped into fasciculi, and probably received from

another individual *in coitu*. The ova are carried out by long convoluted oviducts.

In the earth-worm the external characters of the generative organs may be clearly seen in Hunter's dissections. We perceive, here, that the generative apparatus is more concentrated in the earth-worm than in the leech, and more individualised than in any other animal of the Annelidous class. The three pairs of small opaque organs, which Hunter regarded as testes, may possibly be only "spermathecæ," like the anterior pair in the Naids. They are laden with spermatozoa during the breeding-time. The germinal vesicles and developing ova are found in the larger greyer-coloured cœca; each of which sends out a distinct short oviduct, and these combine into a common oviduct on each side, opening behind the orifices leading from the testes or spermathecæ. If a section of one of these ovarian sacs is made, it is found filled with a spongy matter in the centre, and the ova are situated in this. The common oviduct from each lateral series of ovaria terminates in the fissure upon the sixteenth segment, about one-third from the head. It is interesting to note here, that the condition and function of the oviduct in the earth-worm is analogous to the arrangement of the generative parts in plants. In plants the part answering to the oviduct is a distinct canal, communicating with the pistil, and serving to convey the pollen to the ova; but the ova afterwards escape by rupture of the ovarium, or by what the botanist calls dehiscence of the seed capsule. It is exactly so with the earth-worm; the so called oviducts serve to convey the impregnating principle to the ova, which escape into the abdominal cavity of the earthworm, by bursting through the ovarian sacs. In these sacs, however, there is always found a quantity of spermatozoa in different stages of development; and accordingly the generative organs of the earth-worm are open to two interpretations. The anterior organs may be regarded, as by Hunter and Cuvier, as the testes, or they may answer only to the spermatheca in insects; and, in that case, the true male organ may be that external, spongy part which surrounds the proper ovarium; and this would not be a solitary instance of such an arrangement of the essential organs of generation in the animal kingdom, but one which is very common in the androgynous Gasteropods. However, there is much room for research and experiment to clear up this difficult moot-point.

Both the leech and the earth-worm do enjoy a double or reciprocal coitus; the leech has a true perforated intromittent organ; the earth-worm has not. During the breeding season, however, two imperforate appendages are developed from about the thirty second ring; their base adheres intimately to the cellular tissue; they have no communication with the genital apertures; are developed only at the breeding season; and are deciduous. The second accessory organ is that thickened part of an earth-worm which is situated between the thirtieth and the fortieth segments; it is called the "clitellum," and, when two earth-worms are disturbed *in coitu*, the adhering clitella are the last parts to give way.

With regard to the dorsibranchiate and tubicular Annellides, many of these are diœcious. The sperm-sacs or testes are situated on the ventral aspect, between the layers of the ventral muscles. The development of the ova is more clear and obvious; because they are commonly remarkable for the bright colour of their vitelline mass; and the number of ova is so great, that the ordinary colour of the Annellide is changed at the breeding season. Thus, in the *Aphrodite cirrata*, Sars found that, in February, the three posterior fourths of the body were of a brilliant red colour on account of the great number of ova there accumulated. Neither testes nor ovaria have external ducts; the products of both are discharged by dehiscence into the abdominal cavity, and are excluded by pores situated near the base of the setigerous feet. In the Aphrodite, the ova pass beneath the dorsal scales, and there development takes place. There is but one known species of Annellide that exhibits external sexual characters, viz., the *Exogone* or *Cystonereis*. In the females, the middle segments exhibit pyriform sacs, attached to their ventral surface, which receive the ova after they are impregnated: the male is without these, and is smaller. The genus *Eunice* is viviparous, and the young escape from the ruptured skin of the hinder segments.

A few words now on the developement of the generative products. As to the spermatozoa, these are developed from a great number of cells connected together by a special mass, and studding its surface. Each cell is the seat of development of a separate spermatozoon; this in its growth pushes the cell wall outward, and the filamentary extremities diverge from the common spherical basis of the sperm-cells. Then, by mutual attraction, the tails become amassed together, but finally become liberated, and exhibit the individual spermatozoa.

I shall now bring before you a series of observations, made by Dr. A. Farre, on the generation and other phenomena of the spermatozoa of the common earth worm. He has very carefully traced these appearances, and has accurately figured them by the camera lucid, from which figures the diagrams have been prepared. I will read to you the letter which accompanied the drawings:—

"I think, in reference to the drawings of *Lumbricus*, that it would be more consistent with the objects that I had in view in making them, to limit my explanations in some particulars, for the following reasons. With regard to the accuracy of the figures I have no doubt. Each was drawn from the object under the microscope, with the camera lucida, so as to insure both form and relative size. Those which I left with you are selected from more than 300 figures, most of which were confirmed by several observations. The only difficulty is, in disentangling these from the mystery which is thrown over the whole process, in consequence of all the elements and stages of reproduction being found together at one and the same part of the body, for, on opening the ovary, everything, from the single spermatozoon to the almost perfect worm, may be found contained within it; and the number of observations which I have made has not yet sufficed to put the links together in an unbroken chain. To do this was my object in delaying the publication of my observations. I should at present like, therefore, to go no further than this.

"1st. The plate No. 1 represents what is observed in placing the contents of the testis between two slips of glass. In about ten minutes the whole mass is seen to heave and writhe with astonishing energy, the form of the movement being that of the peristaltic action of the intestines. Everything in contact with the spermatozoa becomes ciliated by them, one end of the filaments fixing itself whilst the other vibrates free. The result is, that if the body to which the spermatozoa attach themselves is fixed, such as the glass, on the margin of a mass of granules, a line of cilia is formed, whose action creates a strong current, and everything moveable is drawn into the vortex, and is seen drifting rapidly along. But, if the body to which they attach themselves is moveable, such as the globular bodies found in the testis itself, or those which occur in every part of the ovary, and which, being extracted from the latter, are placed, for the sake of experiment, amongst the spermatozoa from the testis, then the globular bodies soon become clothed with spermatozoa, whose free ends, moving rapidly, cause the whole body to rotate. A most remarkable object is thus formed, which continues for a considerable time in motion, clearing for itself a free area, and in this it revolves, whilst its revolutions are apparently assisted by the action of other spermatozoa, which, having attached themselves to the periphery of the cleared space, keep up a complete vortex, in which the centre body is partly a passive and partly an active agent. This remarkable property of spermatozoa, in performing the office of cilia, is, as far as I am aware, a new fact, and one which may serve to explain possibly the transference of the sperm fluid, or even of ova, of various animals, along surfaces or tubes not naturally ciliated. The drawing, No. 1, represents the scene which I have endeavoured to describe, but of the energy and vitality of which no mere description can convey any accurate idea. The observations were made in the month of June.

"With regard to the second drawing, showing the curled spermatozoa, I must beg you to use it only as illustrating what is already known of their developmcnt, of which it will supply you with a better serial example than has yet, I believe, been put upon paper. My reason for this is, that I would prefer waiting for these facts, to prove my conjecture right or wrong, before I hazard anything on the subject. In that case, to agree with the present notions on the subject, you have only to turn my drawing upside down, which will make figure 7 the first, and figure 1 the last of the series. Then figure 7 will show the exogenous arrangement of the (supposed) sperm-cells, as proved by pressure or drying; figure 6, the ordinary appearance; figure 5, the supposed expansion of the spermatozoa beginning; figures 4 and 3, further degrees of the same; figure 2, that which other observers consider the usual final arrangement; and figure 1, that which I saw most frequently in regard to the position of the spermatozoa on the spherical bodies usually considered to be the parent developmental sperm-cells,—the latter figure also serving to show the appearance produced by artificially applying the spermatozoa to the spherical bodies found in the ovary.

"The conjecture which I offered, as to the *order* of the changes here depicted, seems to get over the difficulty of an *exogenous* production of sperm-cells, and agrees with what may be observed *to a certain point* in artificially mixing the contents of the sperm sacs with those of the ovisacs. I have no doubt of the *series* of the observations,—the only question is, as to the *right end*."

(Diagrams of the drawings were referred to.)

In regard to the development of the ova and embryo in the earth worm; the ova, when they are impregnated, are discharged from the ovarium and fall into the abdominal cavity, being ultimately pressed on to a receptacle near the anal end of the worm. Dr. A. Farre has traced the development in several cases; and the stages in the development of the earth-worm are very analogous to those of intestinal worms. It appears that some earth-worms are developed before they are excluded, but this is not always the case. The whole of the process, however, is perplexed by a considerable number of parasites, gregarinæ, pseudo-navicella capsules, and others, so that it is one of the most perplexing fields for microscopic observation.

In regard to the leech, the generative phenomena is much less dubious. Mr. Quekett and others have found the spermatozoa developed in the same manner as in the ordinary Annellides, and probably the earth-worm. The ova of the leech are spherical, and exhibit, when found in the oviducts, the usual constituents of ova. There is a germ-yolk with a germinal vesicle and spot, a delicate vitelline membrane, and a chorion. When the ova are received into the uterus the germinal spot has disappeared, intimating that impregnation has taken place; then there is a slight contraction of the vitellus, and a central germ-cell appears, which clothes itself with the yolk. When the yolk has been progressively divided into many large lobes, a large clear cell appears in the centre, before the further subdivision of the yolk takes place, which cell lays the basis of the alimentary canal. The peripheral cells begin to form the dorsal and ventral surface of the integument. A particular spot of the superficies of the spheroidal embryo, which surface becomes covered by ciliated epithelium, is developed into a sucker which communicates with the stomach, and so the embryo nourishes itself with the surrounding albumen. The body progressively elongates, loses its superficial cilia, before it is excluded, and, by the development of the posterior sucker, becomes a little leech without further metamorphosis. It is interesting to observe, that the embryo is first ciliated, and with a mouth only, like a *Planaria*, before it takes on the complete form and characters of the leech.

The leech is oviparous; the fertile ova are discharged in groups of from six to fourteen, enveloped in a nidus or cocoon of mucus. The cocoon is

ovate, two thirds of an inch in length, and half an inch in diameter. It has a rough outer surface, but is smooth and slightly tuberculate within. In the month of August, conical excavations may be observed in the slime at the sides of the reservoir, in each of which there is a cocoon. In a few days after the ova have been thus expelled and protected, the young leeches are extruded. The formation of the cocoon is the result of a rather curious manœuvre in the leech. In the *Hirudo Vulgaris*, when the cocoon is about to be formed, the body is observed to be greatly contracted, both above and below the uterus; the included part swells, then becomes milky white, from the formation of a film, into which the animal, having attached itself by its anal sucker, forces, after some effort, the whole contents of the uterus. This being done, the leech elongates the anterior part of its body, and, thus loosening the enveloping membrane, withdraws its head as from a collar. It sometimes bends back its head, and, drawing the collar forwards, gently aids in its removal. The process usually occupies about twenty minutes. The cocoon is at first very elastic, and has no determinate figure. After the leech has attached it to some adjoining substance, it fashions it with its mouth into an oval form. The points of the cocoon from which the leech withdrew its head are weaker than the rest, and from these the young escape.

In most branchiated annelides, the embryo is excluded as a ciliated spheroidal animalcule. It lengthens, partially casts its cilia, retaining them arranged in cinctures or bands about both extremities. At the anterior end the eyes or eye-specks appear; the segments are indicated on the rest of the body; and the tubular feet and their bristles sprout forth; the annellide afterwards taking on the modifications which distinguish its family, its genus, and, finally, its species.

Thus, in the development of the sea-worms or Nereids, there is something which merits the name of a metamorphosis. Professor Lovén, in August, was surprised at capturing a little creature of the form above defined, girt by a double row of vibratile cilia. No indications of segments had at that time appeared. He thought, at first, that it might be some species of polygastric infusoria; but he found afterwards that the animal had a complete alimentary canal. He kept it long enough to observe other changes, such as the development of a head, with eye-specs, and then the formation of segments, each in four distinct masses; and the succession of these segments, rapidly developed, soon indicated an embryo of the annellate class, and one of the dorsibranchiate order, by the projection of tubercular setigerous feet.

As to the Aphrodite, in February, Sars found a small species, which produced richly-coloured ova, and he traced the successive development of these. He found that the ova escaped from small pores, and were received into a kind of pouch beneath the dorsal scales, and there underwent their development, and escaped. He observed the geometrical division of the rose-coloured yelk, and the clear spot in the centre of each successive division. The embryo is an active locomotive oval mass, with a little groupe of cilia, and an indication of an eye-speck to guide its course; after swimming freely for twenty-four hours the development of segments commenced. In the *Cystonereis*, in which the ova are incubated in marsupial sacs, the development of the animal appears to take place without that amount of metamorphosis which has been observed in other *Errantia*. First, there are two short tentacula, then three; then the animal elongates, and before it quits the marsupium, it presents a very cognizable miniature of the parent. The development of a *Terebella* and of a Serpula, has been described by Milne Edwards; and there, too, he observed certain metamorphoses.

With regard to the class *Annulata*, generally we see that the metamorphosis varies much in degree: thus in the leech the embryo takes on almost at once the characteristic form of the parent; in other Annellata the ultimate form is obtained by a successive development of segments; while in others, again, there is more change of form in the course of development. This should teach us caution in our generalisations as to the metamorphoses of particular classes. The chief point of interest in the developement of the Annellata is that the young of many species, when it has acquired the form of the parent, puts in action a power of parthenogenetic propagation by virtue of the retention of certain unchanged germ-cells or nuclei in the last integument of its body; that it does not develope male or female organs in its own person, but that these are developed in the young propagated by gemmation and spontaneous fission; so that in the Annulata we observe what Steenstrup calls alternate generation, although somewhat differently manifested than it was in the Entozoa or the Acalephæ.

General Medical Annuity or Relief-Fund Society.—At the Annual General Meeting of this Society, held at the Hanover-square-rooms, London, on Thursday, July 26, 1849, G. J. Squibb, Esq., in the chair, Mr. Daniel, of Newport Pagnell, the Managing Director, read an interesting Report, in which he lamented the apathy of the Profession to the objects of the Institution. He also suggested the necessity of founding a permanent Committee in London, which should now be considered the central point. Also, that the Rules and Regulations of the Society should be so revised, as to be rendered conformable to the Acts of Parliament especially founded for the protection of societies of this nature. The receipts for the past year amounted to 553*l*. 10s. 2d. Dr. Gardner proposed the first resolution:—"That the Report now read be adopted, printed, and circulated amongst the members of the Society, together with the balance-sheet." George Kelson, Esq., of Seven Oaks, Kent, seconded the resolution, which was carried unanimously. George Ross, Esq., of Farringdon street, proposed the second resolution: "That a Committee be formed in London, for the purpose of inquiring into the principles of the General Medical Annuity or Relief Fund Society, and that the said Committee shall consist of the following gentlemen, with power to add to their number, viz.:—Metropolitan—Dr. Webster, Dulwich; Dr. Gardner; John Propert, Esq.; James Bird, Esq.; George James Squibb, Esq.; Joseph Wells, Esq.; Peter Martin, Esq.; William Self, Esq.; Edward Headland, Esq.; T. C. Girtin, Esq.; J. H. Tucker, Esq.; C. F. Lord, Esq. Provincial — Dr. Burnett, Alton; Dr. Cowan, Reading; Dr. Roberts, Bangor; W. Lambert, Esq., Sowerby, Yorkshire; Robert Martin, Esq., Holbrook; John Rauson, Esq., Ipswich; Thomas Paget, Esq., Leicester; Francis Elkington, Esq., Birmingham; Charles Smith, Esq., Highworth; David Rice, Esq., Stratford-on-Avon; J. G. Leete, Esq., Thrapstone; J. H. Barker, M.B., Bedford; John Rogers, Esq., Newport Pagnell; E. Daniell, Esq., Newport Pagnell; G. H. Betts, Esq., Watford." Mr. Ross had looked for some time with great interest upon this Society, and he was satisfied that it was of a character peculiarly calculated to meet the wants of the Profession. It was not an Insurance Company, but a co-operative Society, furnishing, in the language of Mr. Daniell, an opportunity for the rich to help the poor. Mr. Ross then entered very fully into the merits of such an Institution, and although it was probable that Mr. Daniell's plan required some modification, its general principles were of the character he advocated; for the parties for whom Mr. Daniell sought to obtain help where those whose circumstances prevented them paying large premiums for annuities. Mr. Smith, of Hepworth, seconded the resolution. Mr. Martin, of Holbrook, proposed the third resolution—"That power be given to the said Committee, to remodel the Rules and Regulations if necessary, with a view of submitting them to the members for their consideration, according to Rule 17, and, in the event of their approval, to consult an Actuary." Mr. Ranson, of Ipswich, seconded the resolution, which was carried unanimously.

Medical Reform Bill.—In the House of Commons, on Friday, July 27, it was announced that a Bill for better regulating the Medical Profession would be introduced early next Session.

RESEARCHES ON INVOLUNTARY SEMINAL DISCHARGES, AND THE DISORDERS ATTENDING THEM.

By H. J. M'DOUGALL, Surgeon, Fellow of the Royal Medical and Chirurgical Society; formerly House-Surgeon to University College Hospital.

DISORDERS AFFECTING THE INTELLECT.

(Continued from page 588, Vol. XIX.)

The intellectual and moral faculties are, in many cases, among the first to suffer from excessive evacuations of the spermatic fluid, whether caused by masturbation, venereal excesses, or involuntary discharges. This disorder of intellect may assume various forms, from slight loss of memory, and diminution of the power of application and of concentrating ideas, to complete mental imbecility; and, when combined with disorder of the moral sentiments, as is frequently the case, these conditions are further complicated by the presence of various hallucinations, proceeding sometimes to such an extent as to render restraint necessary for the patient's safety. Such derangements are generally of a depressed character, showing want of tone in the system; and include what is described as hypochondriasis in its most extensive meaning.

In these cases there are usually present a dread of society, especially of that of females; a sense of incompetence to perform the most ordinary duties of life; a feeling of complete isolation, even in the midst of the most active scenes; a dread of the future, disgust of the present, and remorse for the past. The sufferers wander about abstracted and preoccupied with their own thoughts, generally reflecting on their complaints. When addressed they are irritable and morose. The most trifling circumstances excite querulous anger, especially directed against their relations and friends. They are enemies to all kinds of innocent amusements, being themselves unable to appreciate any enjoyment derived from society, which, on the contrary, constantly reminds them of their misfortunes. On the other hand, such patients eagerly seize every opportunity of talking of themselves, and of their complaints, especially if they can obtain any person with ever so little acquaintance with medical science as a listener. They are then diffuse and prolix in the extreme, dwelling on the most trifling symptoms, and relating with extraordinary minuteness every mode of treatment, rational or empirical, to which they have been subjected.

When hallucinations occur, the moral disorder often takes the form of distrust of relatives and friends; of self-accusation of frightful imaginary crimes, generally connected with the genital functions; or of a feeling of dread of ridicule which the unfortunate patient imagines himself the object of in all his relations in life. In such cases, there are often sudden variations in temper, the depression the patient suffers being by no means constant. One day, perhaps, he may appear to a certain extent merry and cheerful; on the next, he falls under the empire of the most gloomy thoughts and apprehensions. These changes have the most intimate connexion with—indeed, I may say depend upon—the frequency of the discharges, of whatever description they may be, as, indeed, the patients themselves remark when once they are made aware of the presence of such losses; for, in by far the majority of cases, they have not noticed the genital functions themselves, nor have their medical attendants made any inquiries as to their state.

The amount and intensity of intellectual disorder present varies much with differences of age and constitution. It is most marked, or, perhaps, more easily appreciated, in boys addicted to masturbation, than in persons of mature age; and is also very evident in persons who are suffering from spermatorrhœa, who are past the prime of life, and verging on its decline. Most of my readers will call to mind cases, in which boys of great intellectual promise, up to a certain age,—say twelve or thirteen,—quick at learning, and retentive in memory,

—leading their playfellows, and at the head of their class,—active, robust, and hardy,—between that period and the age of twenty-one, disappoint all the expectations of parents and friends, allow themselves to be beaten by others of apparently much less intellectual power, and frequently even fail in passing the ordeals required before entering on the profession or trade for which they were being educated. At the same time these lads become mopish, morose, and irritable, fond of solitude, languid, and unfit for exertion of any kind. Their general health also suffers in many cases; they become pale and emaciated; their faces, the forehead especially, covered with acne; their eyes sunken, and surrounded by dark circles. They complain of heaviness and weariness of the limbs in the morning, and often, if left to themselves, would continue in bed half the day. These disorders have been attributed to rapid growth, original faulty constitution, disordered nutrition, and various other causes. A careful inquiry will show that, in ninety-nine out of a hundred cases, when the symptoms I have just described are present, they arise from excessive masturbation.

There is one remarkable peculiarity about such cases, worthy of especial notice. The patients never look any person straight in the face. They never meet your gaze; and, however much you may endeavour to do so, you can never succeed in looking into their eyes. While talking to you on the most important subjects connected with their health, their looks wander round the room, first looking at one article of furniture, then at another. If sitting opposite a window, they look beyond you, and gaze steadily out of it; and, if they have no other resource, they fix their eyes on the ground, or begin to play with a watch-chain, or anything which gives an excuse for attracting their ocular attention. This symptom is, I believe, peculiar to advanced cases of spermatorrhœa, in which the discharges have been set up by masturbation, and is also present in cases of excessive indulgence in that vice. Spermatorrhœas, however far the case may have progressed, brought on by venereal excesses, clap, or other causes, presents nothing resembling this symptom; which, on the other hand, is almost invariably present where the disease has been brought on by masturbation. A knowledge of being impotent is not the cause of this dread of meeting the eye. Patients frequently come under my notice who are completely impotent, and are quite aware of it, in whom spermatorrhœa has been caused by venereal excesses, or clap, and who boldly avow their complaints, and feel no shame in speaking of them; but this is never the case when masturbation has been the cause of impotency. Whether the continued practice of this vice tends to deprive man of his moral courage, I must leave for psychologists to determine. I merely set down the fact here as I have observed it in practice; and, in my opinion, it is an important one, inasmuch as it at once throws a light on the origin of the complaint. I do not think I have ever been deceived on this point.

Spermatorrhœa affects the intellect of persons in the prime of life less than that of young and old people. The memory is weakened, and there is generally a considerable degree of abstractedness observable. In persons of studious habits, these symptoms are more evident than in those accustomed to the every-day routine of business duties. But one symptom in such patients is peculiarly distressing—their great irritability. The slightest circumstance out of the usual course puts them into an ungovernable fury—of short duration, it is true; but, during the continuance of which, they frequently do and say things to their nearest relations and best friends, which they never cease to regret after the paroxysm is over. Such patients are, generally speaking, the terror of all dependent on them, especially in their domestic relations. Anger is, indeed, a short madness with them, and unfortunately it is excited by little *contretemps* at which healthy men would only laugh. These accesses of rage are attended with the flushing of the face and heat of the head, symptoms which I have previously described. The patients are frequently under medical treatment for these and for other accompanying symptoms referred to the stomach, the liver, or the colon. In many cases, they are married men—fathers of families, and it is by no means necessary that they should be impotent. On careful inquiry, however, it will be found that the sexual powers have much declined, and are very irregular in their demands; at one time intercourse being comparatively frequent, while at another long intervals of weeks sometimes, and occasionally of months, elapsing without a single connexion. Sometimes in these cases there is weakness of the lower extremities, but this is more frequent in the next class of cases, viz., those in which spermatorrhœa affects the intellect in persons advanced in life.

The secretion of semen may go on in persons of strong constitution to an advanced period of life. It is by no means rare for men to become fathers after sixty years of age; of this, most of my readers will recall instances. I need not, therefore, enter into any argument to prove that the testicles continue to act up to the period of three score at least. It is, however, comparatively rare for persons to be affected with spermatorrhœa at this advanced period. The disease probably never *commences* so late in life; and, in cases where it has begun earlier, the patient is generally carried off by some other disease, to which the losses have predisposed him, before he reaches the age of sixty. Spermatorrhœa, after forty, is by no means uncommon, however. In such cases there is great loss of memory, inability to attend to the usual affairs, excessive irritability of temper, and very frequently hallucinations connected with ideas of loss of property, and reverses in life, as well as suspicions of near relatives and friends. In these persons, also, paralysis of the lower extremities is very frequent, and is shown by uncertain gait, stumbling, and, in some advanced cases, inability to walk at all without assistance. The dependence on the will of others, caused by this inability to move from place to place, greatly increases the excitability of temper, so that these patients, with their querulous complaints, are a pest to every one about them. However much their relatives may endeavour to lessen the burden of their disease, and lighten the hours of their confinement, all is set down as nothing, or as done from interested motives. From the failure of memory, present facts and the recollections of early life are confused together, and the patient is, of course, unfitted for any occupation requiring the exercise of even the most limited mental powers. The genital functions are either entirely abolished, or exceedingly irregular, an occasional intercourse, followed by a long period of quietude, being all that the patient is capable of. Nocturnal emissions, also, are rare,—indeed, in most of these cases they never occur,—the most common pollutions being during the passage of urine. The patients seldom refer their complaints to the genital organs, and on the other hand the medical attendant seldom inquires as to their functions. Supposed softening of the brain is the pathological condition to which all such cerebral disorders are referred—a disease which confessedly admits of little remedy, and, consequently, the patient goes down in the list of those to be visited daily more as a matter of course, and for the sake of a gossip, than for any inquiry into his actual condition, which is regarded as hopeless. Things may go on in this state many years before dissolution; the result of some acute disease puts an end to the patient's sufferings. Spermatorrhœa, *per se*, seldom kills. It is sufficient that it makes life wretched. But it does more than this. From the constant debilitating drain on the system, the patient is made more susceptible of the ordinary causes of acute disease; the absorbent system is most active, and takes up indiscriminately, poisonous, as well as healthy matters; the vital powers are low; hence the system is unable to withstand attacks which would scarcely affect a healthier individual with temporary indisposition. These results are undeniable, and are surely sufficient argument for insisting on inquiry into the state of the genital functions in all cases where the symptoms I have described are present. The only objections to such inquiry are, that it is unusual, and that in certain cases the patient would be apt to take offence at such *indelicate* questions. The first is no objection; the second cannot be held a valid one by any man who holds the interests of science, and the recovery of his patient, as the first object of his professional calling.

I have purposely omitted here the influence of spermatorrhœa on suicide, as it is my intention to make that point the subject of a separate paper on a future occasion. In my next, I shall bring forward some cases illustrative of the peculiar symptoms of spermatorrhœa, which I have described above.

24, Henrietta-street, Cavendish-square.

ELEMENTS OF STATISTICAL MEDICINE.

By GEORGE GREGORY, M.D., &c.

[To the Editor of the Medical Times.]

SIR,—The accompanying brief outline of Statistical Medicine was originally intended to form the concluding chapter of the sixth edition of my Work, entitled, "Elements of the Theory and Practice of Medicine." Circumstances, which it is unnecessary here to notice, interfered with its publication in that form. Should you, now, in the exercise of editorial discretion, consider it as worthy of a place in the columns of the *Medical Times*, I would venture, very respectfully, to claim for it, on the part of your readers of riper years, some small share of tender consideration.

The Sketch of Statistical Medicine which I submit, professes only to skim the surface of the science. It was designed for the service of students and junior practitioners. It was intended to show them how the varied forms of disease which Nosologists delight to display, may be formed into natural groups or families. It was written early in 1845, and has remained in my portfolio for half the period prescribed by Horace as the normal term of literary incubation. By such delay, even though thus sanctioned, it may have lost somewhat in interest; but, if it should chance to benefit the junior portion of your numerous readers, without offending the senior, I shall be amply repaid for the labour bestowed upon its preparation four and a half years ago.

I am, Sir, your obedient Servant,

GEORGE GREGORY.

No. 6, Camden-square, Camden New Town,
July 26, 1849.

Importance now attached to Statistical Inquiries—Average Mortality of England, of London—Mortality at Different Ages in Early Life; in the Prime of Life; in Advanced Life—Of Climacterics—Comparative Mortality of the Sexes—Comparative Mortality of Seasons; of Urban and Rural Districts; of Countries and Climates—Trades and Occupations—Comparative Mortality by Different Classes of Disease: Acute, Chronic, and Epidemic—Classification of the Chief Sources of Disease—Mean Duration of Human Life—Fluctuation in the Fatal Diseases of Early Life.

The increasing importance of statistical investigations induces me to think that a chapter which shall bring before the eye of the student, in one view, all the chief varieties of human malady, and afford him elementary instruction in the principal subjects with which Statistical Medicine is concerned, cannot fail to be useful and interesting. In the Introductory Remarks to my work on "Practical Medicine," (page [illegible]) the nature and objects of this branch of science were explained, and, on various occasions throughout the work, the results of statistical inquiries concerning particular diseases were briefly noticed. The chief object of the present essay will be to give the student some insight into the general results which have been arrived at regarding the mortality of the human race under the varied circumstances of age, sex, occupation, season, climate, and locality.

The term Statistics appears to have been first

used about the middle of the last century by a German Professor of the name of Achenwal, and applied by him to express a summary view of the physical, moral, and political condition of States. Some notion of statistical inquiries existed in the times of the Romans. According to Ulpian, registers of population, puberty, age, sex, disease, and death were kept with exactness by the Censors from the time of Servius Tullius to Justinian, comprising a period of ten consecutive centuries. But these registers refer to the citizens of Rome only, and not to the slaves. The results, therefore, apply merely to select or picked lives, not to the average mortality of the people. The nations of continental Europe have long enjoyed the benefits of a national registry; and, in a very imperfect way, our own country was cognizant of its advantages. From the year 1592, weekly Bills of the Mortality of London have been kept by the Society of Parish Clerks; but they comprised not births and deaths, but baptisms and burials. It was not until the year 1837, that the English Government introduced the Registration of Births and Deaths as a measure of national policy. It still applies only to England and Wales. Since the month of July of that year, registers of the births, marriages, and deaths, throughout England and Wales, together with the alleged causes of death, have been carefully kept. We can now, therefore, with the experience of these seven years, supply, from the most unquestionable sources, information both copious and accurate regarding the health of our own population, and the circumstances by which it is chiefly influenced.

Captain John Grant, of London, in 1661, has the honour of being the first writer who ever directed the attention of the world to these matters. He may, therefore, be considered as the founder of Statistical Philosophy. The annual reports by the Registrar-General of England, now amounting to six, enriched, as they are, with the copious and scientific illustrations of Mr. Farr, afford the most valuable aid to the cultivators of this branch of knowledge. In the subsequent remarks, I shall avail myself largely of the information thus obtained, and direct attention in a more particular manner to the medical statistics of our own country.

AVERAGE MORTALITY OF ENGLAND.

The average mortality of England, at the present time, may be stated to be 350,000, and that of London 47,000 per annum. As the population of England and Wales is nearly sixteen millions, and that of London 1,900,000, this gives an annual average mortality of 1 out of every 40 inhabitants for the metropolis, and 1 out of every 45 for the whole country. This is an astonishing decline in the rate of mortality, compared with the experience of former ages, and it presents at the same time a most favourable picture of the value of life in this as compared with other countries. The annual mortality of England, in the year 1700, was about 1 in 25. About the middle of the last century, from causes not well understood, it increased to 1 in 20. From that time to this, it has slowly, but steadily declined. In 1801, it was 1 in 35; in 1811, 1 in 38; and now 1 in 45; so that, in the space of about 80 years, the chances of existence are exactly doubled in London, a progress and final result which may fairly be considered as without a parallel in the history of any other age or country.

In Paris, about the middle of the last century, the mortality was 1 in 25; at present it is about 1 in 32; in Rome the annual deaths are as 1 in 25; at Amsterdam, as 1 in 24; at Vienna, as 1 in 22. The inhabitant of London, therefore, has twice as good a chance of living as the burgher of Vienna. The superior value of life in Great Britain does not appear to attach to any particular district or class of individuals. The upper and middling classes of society, the inhabitants of towns and villages, the agriculturist and the manufacturer, participate alike in the general good fortune.

It will not of course be supposed, that the rate of mortality is equal, or in any way approaching to equality in the various classes of society. Age, sex, and occupation necessarily vary it. It is influenced also, though to a less extent, by season and locality. Our next inquiries, therefore, must be devoted to ascertain the amount of these qualifying circumstances.

AGE.

Nothing affects the rate of mortality in any country so much as age. The proportion of children that die during the first six months from birth is, at first sight, scarcely credible. The deaths gradually diminish to the age of 10. From ten to fifteen may be viewed as the healthiest period of human life. The weakest plants in the nursery have now been weeded out. The dangerous process of teething has been completed. The principal epidemic disorders have, in a great degree, been undergone. Small-pox, measles, hooping cough, and scarlatina have removed their chief victims. Between the ages of 10 and 15, the annual mortality of mankind is nearly uniform. It increases in a marked manner between the ages of 15 and 20. In the subsequent periods of life some irregularities occur, but upon the whole the average amount of deaths continues pretty uniform from 15 to 85, when it suddenly drops. The deaths between 85 and 105, which may be considered as the utmost verge of human existence are few, but they diminish steadily with each year. The following table, extracted from the Third Annual Report of the Registrar-General of England, will show the progressive rate of mortality throughout England, at the several epochs of human life:—

Population of England and Wales (1840)		15,710,270
Births { Males	257,129	501,589
Births { Females	244,460	
Marriages		124,329

DEATHS.

Under 1 month	22,877	
From 1st to 3rd month ..	11,888	
From 3rd to 6th month ..	14,596	
From 6th to 9th month ..	12,067	
From 9th to 12th month ..	11,510	
Total under 1 year ..	76,328	
1 year and under 2 years ..	29,842	
2 years and under 3 years ..	15,952	
3 years and under 4 years ..	11,103	
4 years and under 5 years ..	8,222	
Total under 5 years ..	141,747	
5 years and under 10 years	18,459	
10 years and under 15 years	9,169	
15 years and under 20 years	12,345	
Total under 20 years ..	182,020	
20 years and under 40 years	19,714	
40 years and under 60 years	41,713	
60 years and under 80 years	55,806	
80 years and upwards ..	20,818	
	350,101	350,101

From this Table, we learn that more children die under the age of 1 month than between the ages of 10 and 20 years;—that more than a fourth part of the total annual mortality of any town or district happens to infants under the age of 1 year; and that rather more than half of the annual mortality takes place under 20 years of age. The same Table shows, that more males are born than females, in the proportion of 25 to 24; that the ratio of births to the total population is as 1 to 31; that the ratio of marriages to the total population is as 1 to 126; and, lastly, that there are somewhat more than four births to each marriage.

The following Table, calculated from the first Report of the Registrar-General will serve still further to illustrate the proportionate mortality at the several epochs of life.

Out of every thousand deaths there take place—

Of infants under 2 years of age	..	343
Of children between 2 and 15	..	121
Of adults between 15 and 30	..	113
— — 30 and 50	..	132
— — 50 and 70	..	146
— — 70 and 85	..	118
Upwards of 85 years of age	..	27
		1,000

RELATIVE AGES OF THE POPULATION CO-EXISTING.

The necessary result of the large mortality of infantile life is a marked disproportion in the relative ages of the population co-existing at any given period in any district, town, or country. The attention of statistical writers has, from a very early period, been drawn to this important point, and the greatest pains have been taken, by careful analysis of Population Returns, to obtain accurate results. It has been felt, that almost all the most interesting inquiries in statistics involve the previous determination of this question. A very large induction of facts has shown, that the proportion is pretty nearly the same in all countries. The influx of strangers (or advenæ) into particular localities, and a few other circumstances less important, occasionally affect the result; but these may be overlooked in that general sketch of statistical science which it is my object here to give. Mr. Farr has calculated that the proportion in London, at the present time, is as follows:—Among every thousand of the population co-existing, there are—

	Per Mille.
Of infants and children (under 15 years of age	323
Of adults	622
Of aged persons (60 years of age and upwards)	55
	1000

The bulk of the population, therefore, consists of adults in the prime of life. It may be said, that there are, living in the world, twice as many adults as children, and six times as many children as old people. The proportion ascertained for Sweden, in in 1830, was as follows:—Young persons, 33; adults in the vigour of life, 59; aged persons, 8 *per cent.* Here it will be seen, that the proportion of the aged is comparatively greater than with us.

Such being the relative numbers of the population co existing, it is a curious subject of inquiry, what is the annual *waste* in these three great divisions of human life, (youth, manhood, and old age). It is found to vary in different localities, but the following may be assumed as the average rate for England. There die annually, among those who are under 15 years of age, 40 per thousand; between the ages of 15 and 60, 16 per thousand; above 60 years of age, 97 per thousand. This, with the average of the deaths at different ages in London, for the four years 1838 to 1841 inclusive, is shown in the following Table:—

Deaths in London.		Average of 4 years, 1838 to 1841.
Under 15 years of age, 40 per 1000, or	1 in 25	475
From 15 to 60 ...... 16	1 in 63	341
Above 60 years of age, 97	1 in 10	184
		1000

This law may easily be made applicable to the affairs of common life. Thus, out of every company or association, consisting of 1000 persons in the middle period of life, (aged from 15 to 60,) 16 may be expected to die in the course of one year. Of every thousand young persons, of all ages under 15, 40 may be expected to die annually.

CLIMACTERIC PERIOD.

It has been a favourite notion with mankind, from a very early period, that some years were more influential on human life than others. The doctrine is now known as that of climacteric period or decay, the term "climacteric" being derived from the Greek κλιμαχ, signifying a step or ladder. There is an ascending and descending scale. The ascending climacterics are multiples of 7, viz., 7, 14, and 21. The descending climacterics are multiples of 7 or 9,—viz., 49, 63, and 81. The two latter are known as the grand climacterics. Traces of this doctrine may be found in the writings of Pliny and Aulius Gellius. It may reasonably be asked, what encouragement to such views does statistical science afford? We have already seen that 7 and 14 years may fairly be assumed as important epochs with reference to human mortality. The remaining climacteric periods receive, however, no countenance from statistics. Mr. Rick-

man, in 1831, found reason to believe that the decennial periods of human life were those which possessed a climacteric character. He perceived the mortality at 40, 50, 60, and 70 years of age, to predominate in a marked manner over those of the preceding or succeeding years, and this not in one locality only, but over all England. The more recent returns, being arranged in quinquennial periods, do not enable us to verify or to disprove the notion; but it is discountenanced by the best statists of modern times.

Influence of Sex on Mortality.—The disproportion of the sexes at birth has been already adverted to. It has not varied materially during the first seven years through which the national registration of this country extends, and we may, therefore, presume, that the fact is based on accurate observation. But, further, the same ratio, or nearly the same ratio, (that is, 257 males born to 244 females,) has been observed to hold good in all parts of the world where registers are kept. The disproportion of the sexes, however, striking as it is at birth, soon ceases; for, owing to causes which have not yet been explained, the deaths of male infants under one year exceed considerably those of females, and continue thus to exceed, though in a less notable degree, during the first three years of life. The following Table, extracted from the Third Annual Report of the Registrar-General of England illustrates very satisfactorily this curious fact:—

Deaths in England and Wales among Infants under 3 years of age, between July 1, 1839, and June 30, 1840.

Age.	Males.	Females	Excess of Male Deaths.
Under 1 Month	13,274	9,603	3,671
1 Month and under 12 Months	29,526	23,925	5,601
1 Year and under 2 years	15,304	14,538	766
2 Years and under 3 Years ...	8,125	7,827	298
	66,229	55,893	10,336

Hence it appears that in the first three years of infantile life, there is in London an annual excess of deaths among male children to the amount of 10,336. From another Table, we learn, that out of every 1000 deaths registered in the year 1839-40, there were 240 males who died under one year, and only 194 females. The disproportion of the sexes at birth is thus far more than compensated, even in the short space of three years, by the predominance of fatal disease among male infants. Between the ages of 20 and 40 there is a small excess of deaths among females over those of males. Nevertheless, the disproportion is never got rid of. The result of the whole is, that in every annual register of deaths, those of males exceed in a very notable degree those of females. The following Table shows the amount of such excess in England during three consecutive years:—

Deaths in England and Wales at all Ages.	Males.	Females.	Excess of Male Deaths.
Year ending June 30, 1838	170,965	164,991	5,974
" " 1839	169,112	161,895	7,217
" " 1840	177,929	172,172	5,757
Total in 3 Years	518,006	499,058	18,948

After this statement, it will not appear surprising that the number of females in any country should exceed considerably that of the male part of the population.

The disproportion varies in different countries and districts. The population of London by the Census of 1841 was as follows:—

POPULATION OF LONDON.—1841.

Females	996,558
Males	874,139
Total population	1,870,727
Excess of females	116,419

From this Table we learn, that out of a population consisting of 1,870,727 persons, there was an excess of more than 116,000 females. In round numbers, there are in London 9 females to 8 males.

A fact in statistics intimately connected with this, is the superior longevity of females, a circumstance well deserving of attention, which has been noticed from very early periods, and in all countries. There died in England and Wales, between 1st July, 1839, and 30th June, 1840, 5,247 females of the age of 85 years and upwards, whereas, at the same age, there died only 3,954 males. Among the females who died, 71 had passed the age of 100, but only 40 males. This superior longevity of females is not to be attributed to any difference in the original conformation of the female sex, for men are probably built of stronger materials than women, but to the smaller demand upon their vital powers during the middle periods of life, and doubtless also, in part, to the healthier condition and temperament of the female mind, and to the lesser amount of care and anxiety which falls to the share of the female. The excess of deaths among males during the middle and advanced periods of life, is obviously referable to the greater amount of labour which men undergo, and the more dangerous character of the occupations in which they engage. There are very few diseases common to the sexes, which carry off more females than males. Those which are alone worthy of notice in this respect are, consumption, cancer, and dropsy. The deaths in childbirth form but a very small part of the mortality among females. The result of the metropolitan registers gives only 1 death out 175 cases of childbirth.

INFLUENCE OF SEASON ON MORTALITY.

In all countries season exerts a certain degree of influence on the rate of mortality. This influence is much more strikingly displayed in tropical countries (which have properly but two seasons—the wet and the dry) than in temperate climates, where four seasons are distinguishable. In all healthy localities; that is, in all places not subject to malarial influence, the proportion of deaths is greatest in the cold months.

The following Table exhibits the influence of Season on Mortality in London:—

Deaths in London.	1st Quarter.	2nd Quarter	3rd Quarter.	4th Quarter.	Total.
In 1838	15,611	13,109	11,397	12,581	52,698
1839	11,778	11,023	11,236	11,401	45,441
1840	11,797	10,741	11,044	12,699	46,281
1841	13,713	10,404	10,406	10,761	45,284
Total	52,899	45,277	44,083	47,445	

From this it will be seen, that in London the first quarter of the year is the most unhealthy, then the last quarter, then the spring quarter, while the autumnal quarter proves the most favourable to health. It will be seen, at the same time, that the amount of variation is not great in any year. Indeed, in the year 1839, the difference is scarcely perceptible.

A reference to the Statistical Tables published by the Army Medical Board, will show a very different state of things in Jamaica:—

DEATHS IN JAMAICA AMONGST THE BRITISH TROOPS IN EIGHTEEN YEARS.

(1817 to 1827, and 1830 to 1836.)

During the months of Jan., Feb., and March	1,201
— April, May, and June	871
— July, Aug., and Sept.	1,728
— Oct., Nov., and Dec.,	2,166
Total	5,966

Jamaica is an unhealthy locality, subject to malarial influence in a very remarkable degree. Now, here we perceive that a different order of the quarters prevails in respect of mortality. The six latter months are much more unhealthy than the six early months of the year. The order of the months, in reference to mortality, is as follows:—November, December, and October; August, September, and July; January, February, and March; June, May, and April.

In the East Indies, and in all tropical regions subject to periodical winds or monsoons, the relation of mortality to season follows a yet different law. There it will always be found that sickness and mortality prevail most when the monsoon is at its height. The crisis of a monsoon is characterised by violent storms of wind, thunder, and lightning, and the fall of torrents of rain. The earth becomes saturated with moisture, and vegetation advances with amazing rapidity. This is the sickly season. There are in the East two monsoons: the first, or south-west monsoon, blows from April or May to October; the second, or north-east monsoon blows from November to March. In Ceylon, from the peculiarities of its geographical position, the south-west monsoon is much more destructive to human life than the north-east. The following Table shows the effects of season on mortality in that island:—

DEATHS IN CEYLON AMONG THE BRITISH TROOPS DURING A PERIOD OF TWENTY YEARS (1817 to 1836 INCLUSIVE.)

During the months of Jan., Feb., and March	352
— April, May, and June	627
— July, Aug., and Sept.	452
— Oct., Nov., and Dec.	458
Total	18,889

From this Table we perceive that the second quarter is in this climate the most fatal to human life, then the fourth, then the third, while the first three months of the year are comparatively healthy. The amount of sickness and mortality is almost everywhere proportioned to the quantity of moisture in the air. The months when in Ceylon the greatest amount of rain falls, are April, May, and June. The monsoon is at its heighth in May, and May is the most unhealthy month of the year. Of the 72 inches of rain which fall annually at Colombo, the quantity in each of the months January and February does not exceed 1½ inches. March is the healthiest month of the year. Then follow in succession January and February. Difference among the remaining months is not very perceptible. The deaths in March were 93; in May, 242. The influence of season on mortality is here shown in a very unequivocal manner. Every locality, however, exhibits some peculiarity in respect to this law.

COMPARATIVE MORTALITY OF DISTRICTS.

One of the circumstances which everywhere affects the rate of mortality is the density of the population. Seaport and manufacturing towns which contain a dense mass of population converging to a centre are always more unhealthy than cities in agricultural districts, spread over a wider extent of ground. The health of suburban and rural districts is always greater, *cæteris paribus*, than that of towns in their vicinity. The mortality of hilly districts and mountainous countries is, also, for a like reason, comparatively low. Illustrations of this doctrine may easily be found in the documents already adverted to. The five south-western counties of England contain a population closely approximating, in number, to the population of London. In 1838, the deaths in the metropolis were 24,597, to 15,220 in those rural districts. Now, it is found, that, on every square mile of the 70 which compose the surface of the Metropolis, there live 26,000 inhabitants. In the five south-western counties of England, (including Plymouth, Exeter, and several other large towns,) the number of inhabitants to the square mile is only 230; that is to say, on the same extent of ground occupied by 113 persons in London, there is only 1 in Devonshire or Cornwall. In the years 1838 and 1839, the deaths in certain of the larger cities of England were 197,474; while those in counties, containing as nearly as possible the same numerical amount of population, were only 129,628. The mortality in cities, therefore, is to that of rural districts in England as 197 to 129, or, more correctly, as 144 to 100; the density of the country districts being to that of the towns as 10 to 245. The diseases of childhood are twice as fatal in towns as in country districts.

INFLUENCE OF SOIL AND CLIMATE ON MORTALITY.

It is hardly necessary to say, that the average rate of mortality varies considerably in the different countries of the world. Many circumstances contribute to this general result,—the comparative comfort enjoyed by the mass of the population,

their occupations, the character of their diet, the structure of their habitations, &c.; but the nature of the soil and climate is that which exerts the most obvious and unquestionable influence. It is not the mere circumstance of atmospheric temperature that affects mortality so much as the amount of atmospheric humidity, and the swampy or otherwise unfavourable condition of the soil. It must always be borne in mind, however, that there are great diversities of human constitution adapted to the varying circumstances of soil and climate. The negro can live and flourish in a climate fatal to Europeans. The structure, not of his skin only, but doubtless of the internal organs, fits him for the region which he is destined to inhabit. On the other hand, the natives of the tropics rapidly succumb in the cold and variable climate of England. In all estimates, therefore, of the effect of climate on mortality, the constitutional character of the inhabitants must receive due attention. By reference to the Army Returns, (a) we learn that the mortality among the white troops in Jamaica for 20 years (1817 to 1836 inclusive) was 121 per thousand, while that of the black troops serving during the same period was only 30 per thousand; one-fourth of the mortality of the white race. The mortality of the slave population of that island was then estimated to be only 25 per thousand for all ages, which is the rate of mortality among the inhabitants of London. Sierra Leone, and other stations on the western shores of Central Africa, are destructive in a frightful degree to European life, as the late expedition to the Niger has too painfully proved. Nevertheless, in that same locality there is a large and thriving negro population. There must be something, therefore, in the character of the Negro constitution essentially distinct from that of the European; probably, as different as is the constitution of the Negro from that of the inferior race of animals. It does not consist with the design of this elementary sketch of Medical Statistics to detail the comparative healthiness and unhealthiness of particular localities. A great variety of circumstances must be taken into consideration in determining matters of this description, which can only be weighed and duly estimated by those who devote great labour and patience to the investigation.

INFLUENCE OF TRADE AND OCCUPATION ON MORTALITY.

This branch of statistical Medicine was early cultivated with considerable success. In 1713, Ramazzini, a physician of Pavia, wrote a treatise on the diseases of artificers; and the last century produced many other useful works on the effects of trade and occupation on health and longevity. Some of the best-ascertained results may now be detailed. It has been most satisfactorily demonstrated, that the greatest enemy to health and long life is poverty. In all epidemic visitations,—strikingly illustrated in those of typhus in Ireland, and cholera in England—the mortality falls with tenfold severity upon the poorer classes. But, independent of such rare events as epidemic visitations, the average of deaths among the upper classes of society is always proportionably below those of the working classes. The mortality of the western districts of London is considerably less than that of the eastern. In France, it is confidently stated, that of an equal number of infants taken from among the poor and those in easy circumstances, the proportions of deaths among the former is as 2 to 1. The records of the Equitable Life Insurance Office show, that the annual average of deaths among persons in the enjoyment of competence is not more than 1 in 82. Soldiers are, of all classes of society, the most obnoxious to severe disease and consequent mortality. The result of an investigation made by Mr. Edmonds, an eminent London actuary, into the loss sustained by the British army during the most active period of the Peninsular war, has shown, that the total deaths were 9,900 annually out of a mean force of 61,500 troops, being nearly 160 per thousand of those employed. Of that mortality, about 40 per thousand occurred in battle, or from wounds proving fatal within a short period after a battle, and 120 per thousand were from disease and other causes.

DEPENDENCE OF MORTALITY ON POLITICAL CAUSES.

No fact is better ascertained, than that periods of national calamity are accompanied with an increase in the average rate of mortality, and that national prosperity fosters an increase of population. Villermé, reviewing the great political events which have occurred at Paris during a succession of years, has ascertained, that whenever, from any cause, the mass of the population has materially suffered, not only have deaths increased, but births have diminished, and the mean duration of human life been shortened. In periods of prosperity the results were as uniformly opposed. Such is the intimate connexion which statistical science proves to exist between national and domestic calamity. Nothing more unequivocally demonstrates this principle, than the statistics of a slave population. Under no circumstances is it ever found, that a slave population augments itself. In our West India colonies, in former times, the population was only sustained by large and repeated immigration from Africa. The steady augmentation of the inhabitants of those European States which enjoy political liberties and good government, contrasts strongly, and most significantly, with the diminution everywhere perceptible in the population of the Turkish Empire. The best encouragement to the growth of the population will invariably be found in the existence of domestic comfort and competence, an exemption from mental anxiety and excessive bodily labour, coupled with a feeling of political security of person and property.

COMPARATIVE MORTALITY BY DIFFERENT DISEASES.

We are indebted to Mr. Farr for the following Table, exhibiting the comparative mortality by different classes of disease, throughout England and Wales, during the year 1839; and we may presume that the same rate prevails generally, at all times, in this country:—

DEATHS BY THE SEVERAL CLASSES OF DISEASE IN ENGLAND AND WALES.

Diseases.	Rate per 1,000.
Epidemic and Contagious Diseases......	202
Other Diseases of the General System ..	143
Old Age and Natural Decay............	119
Diseases of the Brain and Nervous System	138
" " Respiratory Apparatus ..	278
" " Heart and Organs of Circulation	10
" " Digestive Organs	62
" " Organs of Urine and Generation	22
" " Superficies..............	6
Deaths by Violence.....................	20
	1000

The deaths by acute, as compared with those by chronic, disease, offer a curious and practically interesting topic of inquiry. The former are liable to great fluctuations, according to the severity of the season, the epidemic character of the period under investigation, and other circumstances easily to be appreciated. But the uniformity of the latter, under all varieties of season, is a circumstance equally worthy of observation. The following table will give a general idea of the ratio subsisting between acute and chronic maladies in reference to mortality.

DEATHS IN LONDON IN 1841.

	Total.	Rate per 1000.
By Acute Febrile Diseases ..	20,144	444
By Consumption	7,326	162
By Violence	1,148	25
By Childbirth	345	7
By the several varieties of Chronic Disease	15,263	342
Sudden Deaths, Malformations, and other causes not specified	1,058	20
	45,284	1,000

From this Table it will be seen, that the acute febrile disorders carry off 44, while chronic diseases destroy only 34 per cent. of the population of London. Including consumption, and those forms of chronic ailment which are occasionally associated with fever, we are borne out in the assertion, that 75 per cent., or three-fourths of mankind, fall victims to fever, in one or other of its varied shapes.

The principal forms of acute febrile disease by which the population of England is carried off, are shown in the following Table, which exhibits, at the same time, the numbers reported to have died of each acute disease respectively, in London, during the year 1841:

DEATHS BY ACUTE DISEASES IN LONDON, A.D. 1841.

IDIOPATHIC FEVERS.		
Typhus Fever	1,151	
Remittent and Intermittent Fever	31	
Small-pox	1,053	
Measles	973	
Scarlet Fever	663	
Hæmorrhage	165	
Inflammation (General)	238	
		4,274
ACUTE AFFECTIONS OF THE HEAD.		
Convulsions (Infantile)	2,778	
Hydrocephalus	1,739	
Cephalitis	615	
Delirium Tremens	83	
Tetanus	20	
		5,235
ACUTE AFFECTIONS OF THE CHEST.		
Pneumonia	3,668	
Hooping Cough	2,278	
Croup, Laryngitis, and Quinsey	489	
Bronchitis and Influenza	885	
Pleurisy	93	
Pericarditis	30	
		7,443
ACUTE AFFECTIONS OF THE ABDOMEN.		
Gastritis and Enteritis	957	
Peritonitis and Hepatitis	118	
Thrush	260	
Teething	913	
Diarrhœa and Dysentery	543	
Cholera	28	
		2,819
ACUTE AFFECTIONS OF THE SUPERFICIES.		
Erysipelas	251	
Rheumatism	122	
		373
Total ..		20,144

It may be useful to present a similar tabular view of the principal and best defined of the chronic diseases by which the metropolitan population is carried off. It is impossible, however, here, for obvious reasons, to attain the same accuracy as in enumerating the acute diseases of the body.

DEATHS BY CHRONIC DISEASES IN LONDON, A.D. 1841.

AFFECTIONS OF THE GENERAL SYSTEM.		
Natural Decay and Advanced Age	3,373	
Debility	1,114	
Dropsy	1,720

SOURCES OF DISEASE.

Careful reflection on these Tables will show, that there are three principal sources of disease and mortality. They are—

1. Original delicacy of frame, or those structural and functional peculiarities impressed on the individual at birth, and transmitted from one or both parents to the offspring. This is the fruitful source of convulsions, of hydrocephalus, of mania, croup, thrush, atrophy, but far and above all, of consumption. These complaints chiefly prove fatal from the period of birth to the age of 25 or 30.

2. The second great source of disease and mortality is to be found in the changes produced in the body by the mere influence of time. The mechanism of the human frame being fitted only for a limited period, gives way by wear. From such a source originate a very large proportion of the cases of apoplexy, palsy, asthma, dropsy, ileus, and aneurism, the several varieties of disorganised heart, liver, and stomach, and that numerous tribe of complaints known to the world by the name of debility and natural decay. This class of disorders proves fatal from the age of 35 to the utmost limit of human existence.

The third great source of disease and mortality is to be found in the agency of the specific morbid and terrestrial poisons, received into the body from without, operating independently of all original contamination, and attacking equally persons of all ages and habits. To this head belong the very numerous and fatal tribe of epidemic and endemic diseases,—typhus fever, remittent fever, small-pox, measles, scarlatina, hooping-cough, and cholera. One fifth of the mortality in London is occasioned by diseases traceable to this source. In tropical countries the proportion is even larger.

4. All other complaints may be arranged under a fourth head, or the accidental sources of disease and mortality, the principal of these being childbirth, accidents and injuries of various kinds, bodily labour and fatigue, exposure to cold, irregularities of diet and intemperance. Gout, rheumatism, erysipelas, delirium tremens, hernia, and a large proportion of the cases of acute inflammation, whether seated in the head, chest, or belly, belong to this head. Complaints, both of this and the preceding division may be looked upon in the light of accidents, as contradistinguished from the more natural forms of decay which constitute the first and second groups intowhich we have thus distributed the diseases of the human body. Nine-tenths of mankind are carried off by the three classes of disease first enumerated, leaving only one-tenth to be the victims of the latter section.

The twelve most fatal diseases to which man is subject in this quarter of the world are the following, and with some slight variation in their relative order, they have been the principal agents in thinning the population, from the earliest periods of which we have authentic records. They are, Consumption, Convulsions, Hydrocephalus, Pneumonia, Typhus, Asthma, Apoplexy, Palsy, Dropsy, Small-pox, Measles, and Hooping-cough. As the mortality in early life is so much greater than that in its subsequent epochs, we may reasonably expect to find the disorders of infantile life occupying the most prominent place in the catalogue of fatal complaints The following Table exhibits the twelve most fatal disorders occurring in the three great divisions of life; viz., its early, middle, and advanced periods; and the position of each disease on the scale indicates the relative proportion which, on an average of years, they bear to each other as the immediate or more obvious causes of death :—

TABLE of the FATAL DISORDERS in ENGLAND.

In Early Life, from birth to 15.	Middle Life, 15 to 60.	Advanced Life, 60 to 100.
1. Convulsions	Consumption	Natural decay.
2. Hydrocephalus	Typhus	Asthma.
3. Teething	Pneumonia	Bronchitis.
4. Pneumonia	Enteritis	Apoplexy.
5. Small-pox	Hepatic affections	Palsy.
6. Scarlet Fever	Dropsy	Dropsy
7. Hooping Cough	Hydrothorax	Debility.
8. Measles	Heart affections	Consumption.
9. Thrush	Childbirth	Heart affections
10. Croup	Cancer	Erysipelas.
11. Consumption	Asthma & Bronchitis	Mortification.
12. Tabes Mesenterica	Apoplexy & Palsy	Renal diseases.

One of the most interesting results which the statistical researches of modern times have disclosed, is the gradual improvement taking place in what has been technically called *the value* of human life. To ascertain what the French call the *vie moyenne*, or the age which a person at birth may be expected to attain, the rule is, to take a given number of persons, (say 1000,) add together the years they individually attained, and divide the product by 1000 (the number of persons). Proceeding according to this calculation, Mr. Finlayson finds that the value of human life, or the average age which 1000 persons in England attain at the present time, is 50 years. At Paris, among the easy classes it is 42. At Florence, the average of the whole population is not supposed to exceed 30 years. The Geneva Tables of Mortality, which have been kept with great care for a century past, show, from 1750 to 1800, the mean duration of life was equal to 34 years, 6 months, and 11 days. From 1801 to 1813, it was 38 years and 6 months; from 1814 to 1833, it was 45 years and 29 days.

Calculations have been made which tend to show, that the expectancy of life, or the *vie moyenne*, among the Romans did not exceed 25 years. If this be so, and there are good grounds for such a statement, it follows that the value, or expectancy of human life in England at the present time is double what it was in the time of the Romans.

Another mode of judging of the comparative healthiness or unhealthiness of any country, at any given period of time, is, to determine the *vie probable*, or the age at which one-half of the population is carried off. It was calculated by Mr. Rickman, that, in the manufacturing districts of England, where the population increases rapidly, but where the seeds of disease are abundant, one half of those born do not attain the age of twelve years. He found that one-half of the males born were dead at 7, half of the females at 17, giving 12 as the average. Such are the effects of density, confined locality, the habits, and occupations of a manufacturing people upon the health of the infantile population. In the West Riding of Yorkshire, the half of those born were dead at 18. The West Riding is a manufacturing district. In the North Riding, an agricultural district, where population is more stationary, the half of those born are not dead till the age of 38. In London, half of the deaths take place about the age of 20.

The increased value of infantile life, of late years, may be estimated by the following considerations :—In the 5 years extending from 1733 to 1737, the proportion of deaths under 2 years of age was as 393 to 1000. In Manchester it is still, from causes already adverted to, nearly as high, viz., 375 to 1000. But throughout England generally, the proportion is now fallen to 295 to 1000, and even in London it is as low as 290 to 1000. This exhibits an improvement of a most extraordinary kind, effected in the course of one century, and it gives strong grounds for supposing that a wide field for further improvement still exists. The cause of this marked increase in the value of infantile life in modern times must be sought for partly in the better nursing and education of children, partly in the influence of vaccination. The fatal diseases of declining life are and have been necessarily much the same in all countries, and in all ages; but fluctuations of a very important kind may be traced in the prominent disorders which thin the infantile population of this and other countries. Hooping-cough which, in the seventeenth century was scarcely mentioned among the fatal diseases of London, destroyed, both in 1838 and 1841, more than 2000 persons. Small-pox, which was the great devastating epidemic of the last century, has now, by the general diffusion of vaccination, lost much of its virulence. As a source of mortality, it has given place to scarlet fever. Any measure, therefore, which, like vaccination, closes more or less completely one avenue to death, serves indirectly to open another. It carries the infantile population forward to that period when it becomes obnoxious to another, and still more formidable tribe of diseases. The weaker part of the infantile population must be weeded out by one or other form of fatal malady. So, in like manner, the encephalic diseases, which were the great metropolitan scourges of early life in the last century, are now less fatal, but in their stead we have an increased mortality by thoracic affections, viz., pneumonia, hooping-cough, and consumption. The only disease, indeed, which retains the same place in the catalogue of fatal ailments now, which it held in 1644, is Consumption. This decay of the respiratory apparatus may be viewed as the great gulf into which all improvements in medical practice, and all ameliorations in the physical condition of mankind in their earlier years, tend ultimately to drive the population.

The law of Nature prescribes that every creature should be carried off by some form of malady. It happens to few only of the human race to sink into their graves after completing the full term of human existence, by a slow and imperceptible decay. By far the larger part of mankind perish by some acute and obvious cause shortening life, and of these the most common is the destruction of the respiratory organs. The lungs appear to be the weakest organ of the human body, and, consequently, that which gives way the first. No measures have ever been discovered capable of giving additional energy to the lungs. We must content ourselves, therefore, with looking upon this as a permanent law of the animal economy. The pulmonary system gives way first, and afterwards those organs supplied by the aorta; the usual order of decay being, first, the brain; secondly, the heart; thirdly, the liver; and, lastly, the kidneys.

I have already had occasion to notice the obligations which all statistical writers owe to the labours of Mr. Farr. The tables of Metropolitan Mortality which the Registrar-General publishes weekly, are models of statistical research, and contain a mass of instruction of which it is scarcely possible to estimate the value too highly. Not only are the causes of death carefully enumerated, but the ages and sexes are distinguished; the weekly births are specified; the localities subject to epidemic or other noxious influences are specially indicated; and the meteorological phenomena which may have contributed, more or less directly, to the hygienic results, are recorded with an accuracy which leaves nothing to desire.

The subjoined Table, with which I conclude this sketch of Statistical Medicine, presents, in one view, the condition of the Metropolis with respect to health and disease, for the first half of the year 1845. It has been prepared with great care, by one who has not spared his own labour in the task; but I beg to disclaim all share of credit in the work.

[The gentleman to whom we are indebted for the following Tables is Mr. Benjamin Smith.]—ED. *Medical Times.*

METROPOLIS.

TABLE showing the BIRTHS and DEATHS for the first HALF-YEAR of 1849, the several DISEASES, BIRTHS and DEATHS of MALES and FEMALES, AGE at DEATH, the DISTRICTS in which the DEATHS occurred, the TEMPERATURE and METEOROLOGY, and the INCREASE of POPULATION.

* Under the head "Zymotic Diseases" are included :—Small Pox, Measles, Scarlatina, Hooping Cough, Croup, Thrush, Diarrhœa, Dysentery, Cholera, Influenza, Purpura and Scurvy, Ague, Remittent Fever, Infantile Fever, Typhus, Metria (or Puerperal Fever), Rheumatic Fever, Erysipelas, Syphilis, Noma or Canker, and Hydrophobia.

Under the head "Sporadic Diseases" 1. includes Dropsy, Cancer, and other diseases of uncertain or variable seat. 2. Tubercular Diseases. 3. Diseases of the Brain, Spinal Marrow, Nerves and Senses. 4. Diseases of the Heart and Blood-vessels. 5. Diseases of the Lungs and of the other Organs of Respiration. 6. Diseases of the Stomach, Liver, and other Organs of Digestion. 7. Diseases of the Kidneys. 8. Childbirth, Diseases of the Uterus, &c. 9. Rheumatism, Diseases of the Bones, Joints, &c. 10. Diseases of the Skin, Cellular Tissues, &c. 11. Malformations. 12. Premature Birth and Debility. 13. Atrophy. 14. Age. 15. Sudden. 16. Violence, Privation, Cold, and Intemperance.

The five Districts of London enumerated in the foregoing Table are as follow:—The West District comprises Kensington; Chelsea; St. George, Hanover-square; Westminster; St. Martin-in-the-Fields; St. James. (Population, 300,711; area, 17·2 square miles.) The North—Marylebone; St. Pancras; Islington; Hackney; Hampstead. (Population, 375,971; area, 20·5 square miles.) The Central—St. Giles and St. George; Strand; Holborn; Clerkenwell; St. Luke; East London; West London; City of London. (Population, 373,605; area 2·8 square miles.) The East—Shoreditch; Bethnal Green; Whitechapel; St. George-in-the-East; Stepney; Poplar. (Population, 392,444; area 8·8 square miles.) The South—St. Saviour; St. Olave, Bermondsey; St. George, Southwark; Newington; Lambeth; Wandsworth and Clapham; Camberwell; Rotherhithe; Greenwich; Lewisham. (Population, 502,548; area, 66·2 square miles.) Total Population, including 3,090 Police on duty, 1,948,369. Total area, 115·5 square miles.

HOSPITAL REPORTS.

KING'S COLLEGE HOSPITAL.

OPERATION FOR CLOSING ARTIFICIAL ANUS.

On Saturday last, we were witnesses of an extraordinary case of this nature, upon which Mr. Fergusson operated.

The following are the particulars which Mr. Fergusson related in the theatre before the operation. Several years since the patient, a young lad, had suffered from morbus coxarius on the right side. The disease had extended to the pelvis; suppuration had probably taken place around the rectum; the coverings behind it, had given way by ulceration, and had left an aperture communicating with an opening in the gut.

The opening existed on the right side between the sacrum and the back part of the ilium; it was two inches in length, and the gut could be seen protruding almost through it,—more especially when the patient made any violent respiratory effort. An orifice existed in the back part of the gut, in which the finger could be placed, and through which the whole of the fæcal matter was evacuated. A bougie could be passed from the anus through this false opening. No fæces ever came *per anum*, and the artificial anus had existed for four years. The disease in the hip joint had become cured, anchylosis having taken place.

Mr. Fergusson stated, that the patient had been sent up to him more as a curiosity than from any idea that he could do anything for him. He, however, thought that he might be able to close the opening, and he should endeavour to-day to cover in a portion of it; and if he succeeded in this, he should finish the remainder at a future day.

He then operated in the following manner:—The soft parts, which were lax and healthy, were dissected upon each edge of the opening, so as to permit them to be brought into contact. The edges of the wound were then well passed, and two harelip needles were introduced, by means of which the lower half of the aperture was well closed without any tension being exerted on the parts. We shall probably have another opportunity of relating the progress of this case.

PROGRESS OF MEDICAL SCIENCE.

FRANCE.

[From our own Correspondent.]

CHOLERA.

While the cholera is fearfully on the increase on your side of the Channel, it is here completely stationary, or exhibits variations of an insignificant character. Thus, for the past week, we have had—

	Deaths in Hospitals.
July 20th	21
„ 21st	17
„ 22nd	9
„ 23rd	8
„ 24th	13
„ 25th	9
„ 26th	9

And in the Military Hospitals 11 deaths, making a total of 97. The mortality of the city continues to range from 15 to 20 per day. The character of the disease, also, has undergone a marked change within the last fortnight. Many cases now present themselves with symptoms of re-action from the commencement; others assume a bilious, and many an intermittent character.

The "sweating sickness," likewise, appears, in many instances, to confound itself with the epidemic, and some eminent Medical men here go even so far as to affirm an identity between the two maladies,—the "sweat" being merely a "cutaneous cholera," and the Asiatic form an "abdominal cholera." This theory is, perhaps, less observed than it may appear at first sight.

M. Levy, head Physician to the Military Hospital of Val de Grace, has recently published the results of his investigations on the pathological anatomy of the disease. They are derived from 150 autopsies, and the most important point—one constantly combatted by Professors Bouillaud and Broussais—is, that the central circulatory system presents frequent marks of derangement, both in the primary and secondary stages of the disease. The lesions, also, are identical in both stages, proving the identity of the disease at all its periods.

The lesions noticed by M. Levy as most frequent are—

1. Considerable distention of the right cavities of the heart.
2. Sub-serous ecchymosis.
3. Purple-coloured suffusion of the left ventricle.
4. Serous effusion into the pericardium.
5. Fluid condition of the blood.

In my last, I alluded briefly to the honorary distinctions conferred on several of our physicians for their labours during the epidemic; and it may be well to record them here.

M. Husson, physician to the Hotel Dieu, and M. Guillot, of Salpetriere, are appointed "officers" of the Legion of Henour. Have been "knighted":—M. Tardieu, of the Central bureau, for his services at the Hotel Dieu; M. Pidoux, for services at La Charité; Legroux, Physician to the Hospital Beaujon; Baillarger, attached to Salpetriere; Mitivié and Trelat of the same hospital; Vincent, Director of la Pitié; Haunosset, of Beaujon; Lebat, a pupil attached to Salpetriere; and Poirson, another pupil of the same Hospital.

The contest between MM. Ricord and Robert, for the Membership of the Academy of Medicine, has terminated in the election of M. Robert, who obtained 49 votes to 40 given to his competitor. A few weeks back each candidate obtained 44 votes, and, as the President has not a casting vote, it became necessary to have recourse to a new election. Little Robert is a good surgeon and an excellent *confrére*, but it is difficult to conceive the motives which induced the Academy to reject Ricord. Intrigue, however, plays a large part in all elections of this kind, and the greater the honour the more energetic, of course, are the efforts made to obtain it. We might, for example, mention a surgeon, a worthy and eminent man, *au reste*, who is known to have prepared his entrance into the Institute by the judicious distribution of "dinners," persevered in for a period of fifteen years. It is not easy to vote against a man at whose table you have drunk at least a tun of champaign.

INJECTION OF THE TUBES OF NERVES.

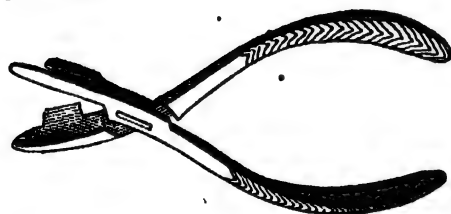
MM. Coze and Michels, of the Strasbourg Medical school, announce that they have succeeded in injecting the primary tubes of the nervous substance, and thus demonstrate an arrangement which many of our most eminent microscopical observers refuse to admit.

A portion of a nerve from the human subject, from a rabbit, frog, &c., is placed on a bit of glass, in such a way that the nervous tubes appear distinctly separate under a magnifying power of 350 to 400. The nerve is moistened with a drop of water, while being spread out on the glass; it is then again moistened with a few drops of chloroform, ether, or spirits of turpentine. The preparation is then covered with another plate of thin glass, but no pressure employed, and the object is examined under the microscope. In some cases instantly, in others after a lapse of twenty minutes, the primary tubes begin to swell; the matter which they contain becomes fluid, and currents are developed with more or less rapidity throughout their whole length. After some time, a fluid, containing some fatty globules, escapes from the extremity of the tubes. The currents may last for some time, or they may cease and recommence; finally, if the experiment be continued, the tubes are at last completely emptied, and present nothing to the eye but two indistinct lines.

The experiments have been repeated by MM. Coze and Michels more than thirty times, and they have shown the circulation to different microscopists in more than 300 nerves. The conclusions which they draw from their observations is, "that the intimate structure of the nervous tissue is tubular, and that the tubes are independent of each other, both in the plexus and anastomoses of the nerves."

LUPUS.

M. Emery, of St. Louis, assures us, that he has employed the cod liver oil with good effects in several cases of the above-mentioned intractable disease. The doses employed by M. Emery are very large. He commences with 100 grammes on the first day, and increases the dose rapidly to 500, which are continued for a fortnight. If no benefit has been obtained at the expiration of this period, the doses are carried still higher.



When the remedy disagrees with the stomach, M. Emery orders the patient to take one or two glasses of Seltzer water occasionally, and he suspends the administration of the oil, whenever vomiting or diarrhœa sets in. When an erythematous eruption appears on the skin, or the diseased parts are attacked by erysipelas with febrile re-action,—when these complications are removed, the oil is again administered in 100 grammes, and the dose rapidly increased to 700, or even 1000. Of 74 cases of lupus treated by this method, several were completely cured, and the majority very much alleviated.

It is, we must confess, a costly and disgusting mode; but lupus is a disease which the patient may think himself fortunate to get rid of at any price.

VARICOCELE AND ENGORGEMENT OF THE TESTICLE.

M. Vidal de Cassis has frequently occasion to treat affections of this kind at the Venereal Hospital. The process which he employs in the treatment is peculiar to him, and may deserve attention. He denominates it "*enroulement*," which we may translate by the term "torsion." A straight, lance-headed needle is armed with a very flexible silver wire, of the diameter of a pin. The patient is in the upright position, and the surgeon commences by separating the varicose veins from the vas efferens, which he pushes backwards and inwards. The veins are grasped by the thumb and index finger with a fold of skin, and the needle is passed behind the vessels, being guided from the index to the thumb of the operator, and carrying the silver wire with it. The engorged vessels are now allowed to fall back, and the index and thumb of the operator pinch up the skin in front of the enlarged mass of veins, and another silver wire, but of smaller diameter than the former one, is passed in the same manner. The patient is now placed in bed, the ends of the wires are cut off, leaving from fifteen to twenty centimetres, and the surgeon proceeds to twist the ends, which gradually brings the wires to bear on the chord; but, as the torsion is continued, the veins are twisted round the metallic loop, and the testicle becomes elevated in proportion to the torsion.

Finally, a small plug is placed on the portion of skin between the two orifices made by the needle; the ends of the wires are twisted on this plug, and the torsion increased by means of a new instrument, which M. Vidal has just invented, and which Charrierre has executed with his usual skill. (I send you a sketch.)

The advantages of this method, according to M. Vidal are, that it exposes the patient less to the chances of relapse, and is less painful than any other. The treatment usually lasts for three or four weeks.

GRANULAR OPHTHALMIA.

Professor Cunier, of Bruxelles, gives his unqualified approbation to the treatment of this malady by the acetate of lead,—a method alluded to in my last letter. M. Cunier has tried, in all the forms of chronic ophthalmia, and in acute catarrhal ophthalmia. It has also been employed, with the best effects, to alleviate the distressing intolerance of light which distinguishes scrofulous ophthalmia.

The great advantage of the acetate of lead is, that we can place it in contact with the affected parts for an indefinite time, or rather, we can incorporate it with them. The nitrate of silver will still continue to be employed, but in a great majority of cases it will soon be superseded by the acetate of lead. Like the former remedy, also, it possesses what is called an "abortive" power in many forms of inflammation of the eye, and its efficacy in this respect is said to be nothing inferior to the nitrate.

TO SUBSCRIBERS.

Subscribers in want of any of the back Numbers are recommended to complete their sets. Cases for binding the volumes, price 2s. each, are now ready for delivery.

New Subscribers will oblige by forwarding their Names direct to the Office, 147, *Strand, or to the News Agents or Booksellers. All Post-office Orders should be made payable to the Publishers,* WM. S. ORR AND CO.

THE MEDICAL TIMES.

SATURDAY, AUGUST 4, 1849.

We lately took occasion to direct the attention of our readers to a subject fertile in important and striking facts, viz., the influence of civilization on disease. We then pointed out that in each successive period of national progress, diseases change, even as change the conditions which they accompany. The ills that flesh is heir to, are not the same for the elder, as for the younger sons of society. In the earlier and ruder ages, the undrained fen, the uncleared forest-land, the recurrent and wide-spread famines, claimed their victims. At a later date, within the narrow compass of walled cities, and amidst the impure residences of an unrefined people, the deadly plagues and fevers of the Middle Ages vexed the souls of men. In our own time and country, the restless spirit of commerce has almost realized the fable of the Assyrian king, and has reared cities in a single day; it has withdrawn men suddenly from the open fields and plains, and has herded them confusedly in dense and ill-assorted crowds. Within the memory of man, vast towns have sprung up where formerly the lonely traveller startled the heron from its stone, or roused the wild deer from its brake. Within the present century we have entered on a different phase of national life; and we must anticipate that the physical and moral conditions of our new social position will increase the frequency of some diseases, will cause others to disappear, and will, perhaps, stamp their impress even on those affections whose origin is irrespective of, and is beyond, them.

Not only in the kind of diseases, but in the mode of regarding them, the earlier and later periods of civilization are to be distinguished. In rude and primitive times, men looked upon diseases as impenetrably and inscrutably obscure; like the wind, they spread where they listed, and no man knew whence they came or whither they went; they were regarded as the arrows of offended Deities, or as the fatal consequences of the curse, which had blasted the earth and wrecked the fair order of the primal harmony. If a few great Physicians pointed to the fact,—that infringement alike of physical as of moral laws brought its inevitable consequence of imperfection and decay, the mass of the people profited little by the lesson. No man looked within him and around him for the source of the evil he endured, but forgot his own unhealthy condition, while he inveighed against the inclemency of Heaven, or cursed the retrograde courses of untimely seasons.

As Science widened and became precise, men began to doubt the truth of this belief. They drained the morass, and the fen fevers died away; they cultivated more plentifully the fruits of the earth, and straightway disappeared the scurvy; they cleansed their cities, and destroyed the plague; they traced out the manifold ills which the impure commerce of the sexes generated, and noted the depressing causes which gave rise to the fatal consumption. They learned how mental and bodily diseases, like natural peculiarities, are acquired by an individual, and may be transmitted to his offspring; and, observing such transmission, they comprehended one meaning of the terrible denunciation, that the sins of the fathers shall be visited on the children. And thus they discovered, that Nature is not wholly to blame; but that we ourselves both breed and nurture a host of maladies, which only need, for their removal, a return to those rules of health which have been neglected and infringed.

The determination of these rules, and the consideration of how they may best be followed out, amidst the multitudinous influences with which this vast organization of modern society surrounds us, constitute the problem of Hygiene. It is no light task to estimate properly the effects which flow from the several discordant elements of modern life—from the fever and the vicissitudes of commerce—from the wear of intellect—from the unhealthiness of trades—from the accumulation of individuals of both sexes into small spaces—from, in fact, any of the innumerable moral and physical circumstances which affect, more or less, all classes of the community. But we can conceive no task so important, none so likely to benefit the people, and to secure to them a greater supply of that which it is the aim and end of all government to furnish, viz., moral and physical happiness and comfort.

At the present moment, it is particularly desirable that the subject of Hygiene should be carefully and impartially investigated by men competent for the task, and who are neither swayed by preconceived speculation, nor by the desire to raise an interest in any one particular direction. For of late years, a set of enthusiasts, carried away by every wind of doctrine, have grievously intruded their vague and one-sided opinions upon us. With some foundations of truth, they have built superstructures of most unstable materials. Each one entreating that *his* panacea may be allowed fair play, and predicting in brilliant colours, the golden age which he hastens to restore.

But, alas! the problem to be solved cannot thus be cut asunder, but must be patiently worked out with yet many years of observation and inquiry. Not in a single element, but in diverse conditions, in a combination of many circumstances, we must look for the varying influences from which diseases spring. Let us hurry on sanitary reforms, repair our sewers, cleanse our streets, and, as far as may be, purify our air; but let us not deceive ourselves with the notion that this is all we have to do,

in order to restore health and long life to our city population. We shall be bitterly disappointed if we expect thus to reduce our mortality to its proper rate, or to place the pale citizen of Bethnal-green on a level with the hearty rustic of Kent or Hampshire.

We are far from wishing to underrate or to fail in acknowledging the unquestionable benefits which must result from the exertions which have been lately made to improve our sanitary condition. But we are afraid lest our Sanitary Reformers should deem that the victory is, or indeed ever can be, wholly won. The establishment of a Board of Health is not the culminating point and terminus of Sanitary Reform. The creation of such a Board is certainly an indication that Government has at length recognised the importance of the subject; but this is merely the elementary and fundamental process by which that most useful public office is to be formed, whose inquiries, no longer one-sided, vague, speculative, and unproductive, but clear, precise, and based on the highest science of the day, are to elucidate the principles by whose aid the National Health is to be purified. Such a Board is not to be exclusively made up of engineers, surveyors, and the other representatives of the more mechanical and executive sciences. These must be indeed the hands of the Board of Health,—the instruments by which it works;—but the head and directing intellect can be derived only from the knowledge and research of those who have made diseases their special study, and who alone are competent to enter upon the difficult investigation of tracing out the causes of a nation's ills, and of attempting to bring back to every man that blessing of Health, without which even Nature's gift of life is shorn of its choicest fruits.

AN AMERICAN'S ESTIMATE OF THE ENGLISH MEDICAL PROFESSION.

Dr. George B. Wood, Professor of Materia Medica and Pharmacy in the University of Pennsylvania, has recently paid a visit to this country, in order to ascertain the actual condition of the Medical Profession here. Since his return to America, he has stated, in an introductory Lecture delivered to his class, what information he has obtained, and what opinions he has formed of the English practitioners of the healing art. The Lecture has just reached our hands, and we deem it our duty to present to the readers of the *Medical Times* an outline of the Doctor's statements, and our own annotations thereon.

After remarking, that the present organization of the Medical Profession in Great Britain has been the gradual growth of her wants and necessities, without any preconcerted or consistent plan—that the organization of medicine here is defective—and that, notwithstanding a vast amount of individual learning, skill, and devotedness, the general economy of the Profession is not upon the same elevated level "as the other great national interests,"—the Lecturer proceeds to speak of the grades existing amongst Medical Practitioners. These, he says, are four, more or less distinct,—Physicians, Surgeons, Apothecaries or General Practitioners, and Chemists and Druggists. To the Physician he accords the first professional status, from being generally highly educated, possessing a high tone of morals, and a polished exterior, all of which characterise the gentleman. In his description of the Professional habits of our Physicians he draws a contrast with those of his own country, and says that the nearest approach in America to the ordinary practice of the English Physician, is that of a Medical man of established reputation in one of the large towns, who wishing to limit his patients, confines himself as much as possible to the giving of advice at home, and consultations abroad. But here the analogy ceases. While the English Physician receives his proper fee at the time of his professional visit, the American notes each piece of service in his book, and sends an account of the whole at stated periods." In fact, our transatlantic brethren hold the honorarium paid at the time of the visit in no other light than a "mercenary service; and that the recipient, while he does not repeat the servile formula, *Remember the Physician*, must have the words in his heart. Brother Jonathan's notions of Professional gentility in this matter are evidently very un-English, and were they propounded to the grave and learned corporation in Pall Mall, would excite unmitigated feelings of hostility.

But, our American brother, in his travels through the British islands, appears to have imbibed the strangest notions in reference to the General Practitioners of Medicine. "While," he says, "they are destined to play an important part in the future medical history of the country, the name of apothecary at present signifies a mongrel compound of doctor, man-midwife, surgeon, and drug vendor; a true Jack-of-all-trades and master of none, willing to play second part to the regular physician; and, though used by the public, yet looked on by them with a sort of good-natured contempt! While he continues to prepare and sell drugs, he has superadded the practice of the different branches of the Medical Profession, and, without becoming a good Medical Practitioner, has ceased to be a good Pharmaceutist." Where, in the name of truth, did Dr. Wood get this information? Did he see for himself the practice of this "mongrel breed" while in England, as he speaks thus confidently about it, or did some wicked wag "cram" him? We thought that our provincial doctors were rather important men in their several localities; but according to this American tourist they are looked upon by the public with a sort of good-natured contempt. The fact is, the name of Apothecary deceives foreigners: they cannot disassociate it from the sale of drugs and chemicals; and the trading establishment of the Company in Water-lane perpetuates the deception. Every one is familiar with the story of Sinbad and the Old Man of the Sea, who fixed upon the unfortunate sailor's back with so much firmness that all his efforts for a long time to shake him off were vain. The name of Apothecary sticks with the same tenacity to the General Practitioners of Medicine, and hitherto they have been unable to get rid of it. We hope ere long, however, that they will meet with success. As English Medical Journalists, we enter our protest against the statement of Dr. Wood to his pupils in the Pennsylvania University, and we trust that our Transatlantic Contemporaries will also endeavour to correct the error into which their countryman has fallen.

The English General Practitioner is not that ignorant person whom Dr. Wood states him to be, but has received an education equal, at least, to the "Physicians" of the United States — the members of the American Medical Association being judges. We admit, that the competition existing amongst our licensing Medical Corporations has retarded the progress of Professional education; but, with all its imperfections, it has attained a higher standard than in the Western Republic. Diploma-mongering there has been carried on to such a fearful extent, that some of the graduates of Universities have received their Doctor's degree without knowing the freezing and boiling points of water; while they have imagined that castor oil was the oil of castor, an animal; and that the solar plexus was situated in the *sole* of the foot! Now, we do not believe the most stupid candidate that ever went up to our College of Surgeons or the Apothecaries' Company was such a noodle as to mistake a plant for an animal, or to suppose that a man carried his stomach in his shoes.

We have thought it right to notice the statements of Dr. Wood, a lecturer of eminence in his country, in order that the erroneous opinions which he appears to entertain in reference to the great bulk of English Medical men, may not be extensively propagated in America; and that those whom he has misrepresented may be stimulated to seek more earnestly for Professional enfranchisement. This, we conceive, to be the grand means of bringing about the climax to which Dr. Wood refers, while the Profession in other countries will, by it, be able to learn, that Surgeons in General Practice are not "a mongrel compound," but an educated, intelligent, useful, and respected class of Medical men.

VACCINATION AND INOCULATION.

We would call the attention of our readers to the able paper of Dr. George Gregory in our last Number, on the "Variolous Epidemic of 1844;" and would beg them to compare it with the Report of the National Vaccine Establishment, published in the *Medical Times* for June 9, 1849. In the latter, we see how little it is possible for a paid irresponsible body to effect, with unlimited means for investigation at their disposal; in the former, what important results may be obtained by the careful examination of a limited number of facts collected by individual labour.

Dr. Gregory and the Board are at issue on a question of no small importance. The Legislature has interfered to prevent inoculation. Dr. Gregory maintains that inoculation, if performed under certain circumstances, would vastly diminish the mortality from small-pox; and, in support of his assertion, adduces a large amount of carefully collected evidence. The Board, on the other hand, bestow their praise on the Legislature, for having made inoculation illegal. But the evidence on which they found their opinion is carefully concealed; their

laconic epistle informs us only, that they have received numerous communications from British and Foreign correspondents; that they have supplied from the Establishment over which they preside 174,991 charges of lymph; and that small-pox has been very prevalent in the West Indies; but, of the nature of the voluminous communications they have received, or of the particulars of the Epidemic, the Report affords us no information. Surely such a document is utterly unworthy of the Presidents of the Royal College of Physicians and Surgeons, the Senior Censor, and the Registrar of the former. Is it possible that these officials can be paid some hundreds yearly for appending their names to such an inane production? If unable or unwilling to investigate the subject of vaccination in all its bearings, to analyse the immense mass of materials they have, or ought to have, in their possession, we would entreat these exalted members of the Board, for the interests of humanity, to make way for men, if not more able, at least more willing, to do the work for which they are paid.

The subject of Dr. Gregory's paper is of too great importance to be allowed to sleep. It is true, that vaccination has greatly diminished the mortality from small-pox; still, it is a fact, that a few years since near 2000 persons fell victims, in London alone, to the ravages of this frightful malady. The accomplished Physician of the Small-pox Hospital, whose position alone ought to command attention to his statement, even though unsupported by the powerful evidence he has brought forward, assures us that we are sleeping on a volcano; that to-morrow may bring to our homes an enemy as much to be feared as that which now stalks uncontrolled among us; that we have excluded, by Acts of Parliament, the means of preventing its inroads, and lean on a reed, which will give way at the moment when we the most need its support; yet, with these assertions ringing in their ears, and the evidence before them on which they rest, the venerable Presidents doze in their chairs, or issue, for the information of the Profession and the good of mankind, the miserable document to which we have referred, yclept the Report of the National Vaccine Establishment.

REGISTRATION OF CHILDREN BORN DEAD.

We transfer to our columns a letter from "A Surgeon," which appeared in the *Times* newspaper of Friday last. The writer appears to have discovered an omission in the clauses of the Registration Act, by which the lives of many have doubtless been sacrificed. The subject must, in the course of the next session of Parliament, be brought under the notice of the Executive. In the meantime, we trust our readers will communicate to us any evidence bearing on the subject which may come within the sphere of their observation. It would be a point of considerable interest to ascertain the relative numbers of children born dead, in cases attended respectively by uneducated practitioners and medical men.

"Permit me," says the writer, "to draw your attention to a fact of so much importance, that I can scarcely understand how it has escaped the vigilance of the Legislature.

"The registration of births and deaths has been productive of immense medical, physiological, and statistical advantages. The influences of locality, climates, seasons, sex, habits, occupation, &c., have been recognised and appreciated; sanitary regulations, sewerage, &c., have been made important matters of consideration; yet one circumstance, and an important one, too, has been overlooked.

"The registrars of births and deaths are directed to obtain medical certificates of the death of children born alive, but no legislative enactment desires them to procure a medical certificate for those born dead. The latter are usually taken away by the sexton and quietly interred.

"Now, Sir, take the case of a child born alive and dying in three or four hours after birth, and being secretly interred in the manner described. The sexton is told that the child was born dead, and the law requires no medical certificate,—all is hushed in the tomb, and the world knows nothing of the matter! This, I am fully persuaded, is no infrequent affair. The facilities for certain commissions may be conjectured. I have heard of a midwife who was so particularly unfortunate in the loss of the 'little strangers,' that her practice grew too large for her."

THE NATIONAL INSTITUTE.

Our readers will perceive, by an Advertisement in our columns, that the Annual General Meeting of the Members of the National Institute of Medicine, Surgery, and Midwifery, is appointed to take place on Wednesday next, at the Hanover-square-rooms, at seven o'clock, p.m., precisely. Considering the important position in which the Institute stands, as representing the interests of the General Practitioners in the Conference Committee, it is very desirable that the Members generally should attend on that occasion, as doubtless matters of much importance will be brought before the meeting on the subject of Medical Reform.

THE OPERATIVE SURGERY OF JOHANN FRIEDRICH DIEFFENBACH.

Edited by Dr. BUSHNAN.

The suggestions of several esteemed friends, and the marked satisfaction with which this Edition of Dieffenbach's Surgery has been received by the Profession, have induced me to depart, in some degree, from the plan with which I commenced it. I propose, then, to render the Work still more complete and acceptable, by comparing, when necessary, the views and opinions of the Author with those of other authorities, and by considering the value and importance of the practices they severally advocate.

To effect this object, the co-operation of a practical Surgeon has become necessary—of one not only deeply read in the literature of his science, but ably practised in the manipulations of his art. The services of such I have happily secured; and for the future the Work will be published under the joint Editorship of myself and Mr. Ure, *of Bloomsbury-square, Fellow of the Royal College of Surgeons of England, and Surgeon to the Westminster General Dispensary.—J. S. B.*

(Continued from page 78.)

III. THE REMOVAL OF FOREIGN BODIES WHICH HAVE PENETRATED THE TEXTURES.

1. *The Extraction of Foreign Bodies from Wounds, or from Suppurating Canals.*

A vast multitude of instruments have been contrived for the removal of foreign bodies from the living organism,—a manifest proof of the difficulty and importance of the procedure. Most of these apply to the removal of bullets, by far the most momentous. They are chiefly forceps, scoops, or hooks, and also gimlets for boring holes into those imbedded in bone, in order to facilitate extraction. Many are useful, many superfluous, and others detrimental. The simple are the best.

The most eligible ball-extractor, according to my experience, is a straight, uniformly round, strong, forceps, fashioned like a straight polypus forceps. Its branches and handles must be longer, and its thickness more than [illegible] forceps, that it may not break. It must, for the same reason, be without perforations, its inner edges armed with strong teeth; externally, finely polished, so as not to irritate the raw surface.

In addition to the forceps, the surgeon ought to be provided with two bullet-scoops, a strong silver probe, a large syringe, a probe-pointed bistoury, and blunt hooks.

The patient ought to be put in the same position as that in which he received the wound, otherwise muscular fibres, fasciæ, tendons, get misplaced, and tend to perplex the passage through which the projectile entered. Should inflammation have assailed the wound, it must be treated in the usual way, and no operation attempted till its subsidence.

The act of exploration demands the utmost foresight, all noise being excluded, so that the surgeon may clearly distinguish what the probe strikes against. If the ball is to be felt plainly, it is to be extracted. The forceps smeared with oil are introduced shut, opened when they reach the ball, made to catch hold of it, and, with a few gentle turns, gradually withdrawn. Care must be had not to injure the sides of the wound. Sometimes the ball may seem to be deeply seated when really near the surface, and *vice versâ.*

The dilatation of the canal or tube formed by the track of the ball is, in general, highly prejudicial; but the wound in the integument may be dilated when it will not admit the forceps. The position that a gun-shot wound should be transformed into an incised wound is false; to enlarge the wound is to increase the danger. Only in the instance of great extravasation, of loose portions of bone, or of shells, or accumulations of pus, is dilatation permissible. (See "Dilatation of Wounds.") If the ball has penetrated a bone, and cannot be got away with forceps, it may be eased out with a gouge. The suggestion of using quicksilver, to form an amalgam with the lead, is most objectionable.

If there be no immediate prospect of removing the ball, all further attempts should be postponed until suppuration is established, when they may be renewed with some likelihood of success. Frequently balls heal up within the bone, are overgrown with osseous deposit, or else encysted in the soft textures.

In other cases the ball separates of itself, and comes away after the lapse of months, when the tube has been rendered wider by the process of suppuration, the fat and muscles absorbed, and the patient accustomed himself to lie upon the corresponding side.

Occasionally the ball cannot be found. It may have deviated from its track, swept round a bone, or taken a totally different course than could have been expected from the direction of the tube. Under such circumstances all interference is futile. Are there two openings in a limb? The lesser is the inlet; the greater the outlet. Of course, probing is out of the question, for the ball is escaped. But yet, despite of two openings, a ball may be present. I was called in consultation with Dr. Casper to a young Russian, who had shot himself. There was an opening on the chest anteriorly, and another on the back, both of the same size. At the cadaveric inspection a bullet was found in the thoracic cavity. The pistol, therefore, had been loaded with two balls. Of these one had passed through, while the other remained. Should the ball be lying beneath the integument on the opposite side, all groping in the tube formed by its track is improper; nothing more is needed than to make an incision through the skin and extract it. Bony splinters ought to be left until detached; otherwise dangerous bleeding may result. If the bone is fractured, no search should be made. Wounded arteries must be secured with ligature a little above the wound, which is not to be disturbed. Portions of wadding are to be removed with hooked forceps, ball-drawers, or bent hooks. It may be laid down, however, as a general rule in all the above cases, that the less interference the better.

When balls are driven into the surface of the skull, they may be loosened with a chisel or with

Heine's saw: when the inner table is perforated, and the bullet wholly or to a great extent forced inwards, the aid of the trephine will be required for its withdrawal. The surgeon ought not to go in quest of bullets lodged within the chest or abdomen; he may, if accessible, remove them from the wound, but make no attempt at dilatation. Afterwards the edges should be carefully brought together and retained in apposition by strips of adhesive plaster and a compress, even although other foreign bodies be infixed.

The extraction of balls, grape and the like, from the cavity of a joint or the head of an articulation, is attended with much difficulty, and only admissible when the ball will readily yield, as amputation is generally indispensable before the occurrence of inflammation.

Small pistol-shot, deer and hail-shot, do far less mischief than those of greater diameter. They either perforate the limb, or remain and are healed in the flesh. They ought to be removed only after recent injuries, when they can be easily laid hold of with dressing or polypus forceps. Hail-shot may be let alone, if deeply inserted; but, if superficial, picked out with a curette.

Angular fragments, as those of bombs and grenades, chopped lead and nails, splinters of the carriages of cannon, or of ships, (during sea-fights,) cause the most complicated lacerations, and their excision by dilatation is as urgently indicated, as the opposite, or passive plan, in the instance of smooth spherical shot. In every case the incision is to be made in the longitudinal axis of the limb, in the course of the muscles, nerves, and blood-vessels, preparatory to the removal of the extraneous substance, which must be done with extreme circumspection.

Sharp pointed bodies, as the ends of swords, nails, and the like, are more readily extracted than bullets, because more freedom may be used in incising the wound, and in tracing with the probe. For this purpose, a dressing forceps is alone requisite. I have often been at considerable pains in removing the points of rapiers which had entered the body during duels. A portion of a two-edged sword, the length of the finger, was once carried with such vehemence into the body of one of the lumbar vertebræ from behind, that, although the broken end protruded, I was obliged to use great exertion to remove it. The wound got well without any untoward symptom.

Arrows driven into the body, armed with barbs, barbed hooks, or other metallic hooked implements, are to be taken out in the same way as they entered, after previous dilatation by means of a cutting instrument. If the missile has reached the opposite side, a counter-opening may be made for its exit.

Needles, whether entire or broken, which have penetrated the flesh, need no extensive section for their removal. If the needle is lying lengthways, I usually force it out by its point without cutting, namely, by simply pressing up the skin with my fingers against the two ends. So soon as the point makes its appearance, it is grasped with forceps, and the whole withdrawn. I thus extracted a large needle from a lad, which had passed through the urethra backwards to the neck of the bladder. The patient having been placed, as in the operation of lithotomy, I inserted one finger into the rectum, exercised counter pressure with the fingers of the left hand upon the gut, and, having brought the point into view, plucked out the entire needle with forceps. Should the needle not be discovered after incising the integument, and careful probing, the wound must be left to suppurate, and further trials made during the employment of poultices.

Fragments of glass or porcelain ought to be removed forthwith by incision. As the external wound is, for the most part, complicated, incisions cannot do harm. Great delicacy is required, so as not to crush the broken fragment with the forceps during extraction. Suppuration is to be afterwards promoted, lest any particle be left, and prove a future source of nervous irritation.

Grains of powder must be picked out with a full-sized cataract needle, or with the point of a fine scalpel.

In the instance of poisoned wounds excision is the only sure course. If impracticable, the parts should be bathed with tepid water, freely scarified, set to suppurate, or covered with poultices medicated with solution of caustic potash. After the bite of a rabid animal, energetic suppuration ought to be kept up by the agency of powdered cantharides, applied topically, ointment of the same, and, subsequently, mild resinous dressing. The cauterisation of poisoned wounds is most objectionable practice, inasmuch as the resulting dry eschar serves to retain the poison in the system.

IV. THE REMOVAL OF FOREIGN SUBSTANCES HEALED UP WITHIN THE BODY.

In cases of this kind, where no annoyance is created by the presence of the foreign body, the best plan is to let it alone. Where, on the other hand, accidents arise, either from its pressing upon a nerve, or from its approaching a joint and impairing its mobility, or from its beginning to cause shooting pains, measures ought to be taken for its removal. A ball often makes its way to the opposite side to which it entered, and can be there distinctly felt.

The patient is to be placed in a recumbent posture, and so adjusted as to relax the muscles of the part implicated, that the surgeon may be enabled to feel the ball. Should he fail in doing so, but perceive, on pressing some suspicious spot, that considerable pain is complained of, let him plunge a pin, such as is used for transfixing insects, the length of the finger down through the flesh. If resistance is felt in a situation remote from bone, and a sound emitted on a gentle tap being given with a small hammer, he may rest assured the ball is there, and will not have to operate in vain. I have in this way discovered balls very deeply imbedded.

The patient being properly secured, the incision may be carried the length of two inches, if the ball be near the surface; but, if profoundly lodged as in the thigh or buttock, it may extend to three or four inches, always following the course of the muscular fibres, blood-vessels, nerves, and tendons. In the proximity of joints, the cut need not be larger than will admit a straight polypus forceps. It will often prove advantageous to make, with a small narrow knife, a minute incision several inches below the articulation and below the ball, thereby form a punctured channel, and remove the ball according to the subcutaneous method. The utmost caution, however, is necessary, so as not to open the capsule of the joint, or injure the vessels and nerves.

Should a ball create disturbance after a lapse of several years, this is probably due to necrosis or caries. Here the surrounding parts will be inflamed and swollen, and the indication not to disturb the ball, but to further suppuration by means of hot poultices. When this is established, an incision may be made, the ball extracted, and suitable treatment adopted.

A foreign substance which has tarried long in the organism becomes invested with a tough capsule. This ought to be slit across, and after the withdrawal of the ball its posterior wall divided, and sides freely scarified, as being little susceptible of inflammation. When these precautions are not attended to, a cavity is left after the closure of the wound, which may form a secreting surface, and lead to troublesome consequences, at any rate, to re-opening of the wound.

I have repeatedly, by the aid of small incisions and forceps, extracted from the hairy scalp the teeth of horn and tortoise-shell combs, which had remained fixed beneath the skin for years, and caused much inconvenience; in like manner, rusty needles, from various parts of the body, which had got broken by the action of the muscles.

Sharp-pointed substances, as fragments of nails or glass, when infixed in the soles of the feet, the palms of the hands, or the bends of the fingers are apt to occasion much distress. I removed from the sole of the foot of an English officer, a long splinter of glass, which had been healed in, and caused a deal of suffering. It is often necessary to excise, at the same time, hard prominent star-like scars, in order to restore the integrity of the part, and more efficiently remove the extraneous substance. A young girl, who was afflicted with epileptic fits, spasmodic contraction of the arm, with wasting, had a number of irregular cicatrices in the hand and bend of the fingers, which were simultaneously drawn together with and through the spasms. It was stated, that she had fallen upon her hand among glass many years previously. Expecting to find splinters, I dissected out the cicatrices, and discovered, in the firmest of the number, a slip of glass resembling a fish scale. This had evidently determined all her ailments, for the epilepsy and spasmodic contraction ceased, and she recovered the perfect use of the limb.

THE EXTRACTION OF FRAGMENTS OF DEAD BONE.

The interference of surgery is seldom required until the necrosed bone is separated from the adjunct parts by a distinct line of demarcation internally. Much benefit will be derived from judicious medical treatment. Thus, tonic remedies, in conjunction with phosphoric acid, and also alkaline baths and poultices, to favour exfoliation, and induce liquefaction of the callous integument, will be found highly serviceable. When the bony particles get loose, perforate or project beneath the skin, their removal may be accomplished by a small incision. More persons, however, have lost their lives or their limbs by premature attempts to remove dead, or partially dead, pieces of bone, than been relieved by such operations. The process of necrosis requires, at least in the instance of the large bones, years for its termination, as regards unhealthy individuals. All efforts to accelerate merely tend to retard, nor are they exempt from danger to patients reduced by protracted disease. If the *sequester* held only by the soft parts, keeps up inflammation and abscess, it will be right to divide the skin, or dilate a pre-existing aperture, and then seize the bone at one end with forceps and withdraw it. In general, the necrosed fragments of the superficial layers get uplifted by the granulations at the base, and compress the skin, which is thereby attenuated and easily ruptured. During the chronic progress of necrosis of an entire long bone, of which the articular ends pass into the recent structure, the old dead portion is so firmly incased, as not to be readily thrown off. Here patient forbearance is requisite. The outer opening may be dilated with sponge tents, and trials instituted to bring away piece by piece; and small bullet-forceps, similar to polypus forceps, or a gimlet, employed, provided the fragment is loose. If the osseous cavity be extensive, the dead portions may be either extracted or crushed by means of a lithotrite. I have more than once excavated a *sequester*, half as long again as the finger, from its recent bony envelope in the tibia, without previous dilatation of the *cloaca*, by the help of a watchmaker's drill, to which a tubular trephine, of the size of a swan-quill, was attached.

As in the cylindrical bones, so likewise in those of the cranium, are all manœuvres to get rid of dead fragments with saw or chisel contra-indicated. Exposure of the necrosed part by a linear cut where the bone is no longer protected externally by periosteum, is the sole operative procedure to be sanctioned; even a crucial incision is too much. Under the employment of moist warmth, exfoliation is more rapid than in the case of the long bones.

THE CHOLERA—ITS PROGRESS AND MODES OF TREATMENT.

This disease during the past week has been making considerable progress both in London and in the provinces. The mortality in the metropolis from this cause is stated by the Registrar-General to amount to 783, being 105 above that of the preceding week, and nearly all the cases reported are attributed either to bad drainage, deficient ventilation, improper food, or intemperate habits. During the past week numerous letters have appeared in the *Times*, in which various remedies are proposed to arrest or cure this disease, and, for the benefit of our readers, we give the following abstract of them:—

"Tyro-Medicus," Glamorganshire, states a case

in which the best olive oil, taken internally, appeared to effect a cure. The patient was a "Latter-Day Saint," and medical advice being contrary to the rules of his religion, the elders administered, as a religious rite, a cup of the best olive oil. Vomiting presently commenced; a second cup was given, the same operation ensued, perfect tranquillity pervaded the whole system, and the patient expressed himself quite cured. The following morning he was up walking about.

"One who has had an Attack of Cholera," and who has been many years in India, bears his testimony to the efficacy of copious draughts of rice water, at the commencement of the disease; and, during its latter stages, the use of salt and ice. He considers that nothing predisposes persons more to an attack of cholera than vegetable food, especially potatoes.

Mr. C. Rodney, of Old Burlington-street, states, that patients in a state of collapse have submitted to the vapour bath, and, in less than a quarter of an hour, the muscles have become relaxed and the dangerous symptoms subsided, leaving nothing more than weakness to be recovered.

Mr. Owen Evans, of Wilton-crescent, Belgrave-square, relates two cases in which he employed calomel, hydrochlorate of morphia, cajaput oil, and chloric ether, with great success. "Medico-Chirurgus" also speaks in high terms of calomel and opium combined, as a remedy in cholera.

"Medicus" considers the disease to be hæmorrhage, *i. e.*, "that the serum of the blood is separated from the crassamentum, and the capillary vessels pour out the former from the mucus membrane of the stomach and bowels, and that those of the skin also lose their power. The larger quantity that is discharged from the former is owing to the heat being so much greater than on the surface; and that which is called cold sweat is no sweat at all, but an exudation of serum. Taking this view of the case, such remedies should be employed as are calculated to check ordinary hæmorrhage, such as iced water, freely administered internally, as well as sponging the whole surface of the body, in the first place with cold water, and then wrapping the patient in a wet sheet (cold), and covering him with blankets. The effect of this will be to check all further exudation, by which you will generate heat, and natural sweating will be restored, as well as the secretion of the liver, kidneys, &c. The usual styptics may be employed, in addition to the above treatment." This writer objects to the use of brandy, opium, warm applications, and the great change of diet so frequently recommended by the Profession. He also considers the exhibition of olive oil worth trying.

Dr. Edward Johnson, of Umberslade Hall, strongly recommends the "wet sheet practice." The following is the process:—

"Everything having been removed from the mattress, a pillow is placed upon it for the patient's head. Upon the mattress, and extending over the pillow, two blankets are spread. On these blankets is placed a sheet, previously dipped in cold water, and then wrung out as dry as possible. The sheet should extend as high up as the blankets, but need not reach lower down than mid-leg, and should be wide enough to meet and overlap over the patient's body. Two large towels, one under and one over the body, meeting at the sides, and extending up to the neck and down to the knees, are an excellent substitute for the sheet when the sheets at hand are inconveniently large. A tablecloth about five feet square will also answer very well.

"The sheet having been spread upon the blankets the patient lies down upon it, perfectly unclothed, and upon his back, his head resting upon the pillow. An attendant now approaches on the left side of the bed, and, first puckering the sheet from the back of the head down to the back of the neck, reaches across the patient's chest, seizes the right upper corner of the sheet, brings it tightly across under the chin to his own side, and tucks it well and evenly under the left shoulder, where it joins the root of the neck, and under the point of the same shoulder. He now reaches across the body again, and brings all the rest of the right side of the sheet over to the left side, where he tucks it well and evenly under the patient. The attendant now passes to the right side of the bed, and proceeds to bring over the body and tuck in the left side of the sheet precisely as before. He now treats the upper of the two blankets precisely as he has treated the sheet, and finally the under blanket also. But in the blankets the feet and legs must of course be included, and the loose blanket-ends be tucked under the heels; and their upper ends be so close round the neck as to exclude the air. Four, five, or six blankets, doubled, should now be laid over all, extending from the chin to below the feet, and these superincumbent coverings should be pressed down closely against the sides, and a napkin be placed under the chin to prevent the tickling effects of the woolly fibres. If necessary, a small feather bed, or eiderdown quilt, may be added. Before the process begins, the arms of the patient should be extended by his sides. The great point is to seal hermetically the upper end of the trunk, over the shoulders, and round the throat and neck, so that the hot air within cannot escape, nor the cold air without find any entrance. A wet folded towel may be placed on the head, and re-action expedited by giving the patient hot tea through a glass syphon. When the patient has become thoroughly hot, or has began to perspire, he should be placed in a tub, and have one large pailful of water at 65° Fahrenheit dashed over him. He should then be rapidly dried, and placed in bed in the ordinary manner. This process may be repeated at the discretion of the Medical man, and is by no means incompatible with the simultaneous use of any drug which it may be thought desirable to exhibit."

Mr. J. J. Lemanach, of Margate, says that himself, mother, and many others, were rescued from the power of Asiatic cholera by the following simple means:—two grains of calomel, mixed with a little sugar, taken every ten minutes, and continued till the discharge from the bowels was arrested, and copious salivation induced.

"M. R. C. S.," Wandsworth bears testimony to the efficacy of Mr. Child's treatment of the disease with ether and opium in combination. The formula is as follows:—Tinct. opii ♏ xxf.; sp. eth. sulph., ʒi., mixed in a wine-glassful of water, for an adult. If the first dose is rejected, the second is to be given in ten minutes or a quarter of an hour; and the Writer says he has never yet known it to be returned. In the premonitory stage of the disease he recommends a dose of sulphur, mixed with a few grains of sesquicarbonate of soda.

We have thus given an epitome of the opinions of the various Correspondents of the daily *Times* on the treatment of cholera, and it will be at once seen that no settled or satisfactory method has yet been adopted. Every Practitioner appears to have his own favourite remedies, which are sometimes successful, at other times inert. We have in two severe cases found opium and cayenne pepper a most useful combination. We gave 5 grains of the soap pill with three of cayenne pepper immediately, and, this being rejected, repeated the dose in a quarter of an hour; in addition we prescribed an effervescing mixture, to be taken every half hour, in which was contained a drachm and a half of tinct. opii. P.L. The cramps under this treatment speedily subsided, and the rice-water evacuations ceased. We also ordered boiled rice, in which was a small quantity of brandy, as recommended by one of our Correspondents, and found it agree well with the stomach. The patients were man and wife, and had been ill with premonitory symptoms three days previously. The friends of the woman considered her dying when we first saw her. Both recovered.

MR. SKEY AND MR. CRITCHETT ON THE TREATMENT OF ULCERS.

[To the Editor of the Medical Times.]

SIR,—I apologise for again intruding on your columns the somewhat heavy performances of myself and Mr. Critchett.

There is an air of self-contentment about the reply of the Author on ulcers to my letter, savouring of his first brush with me in the work itself,—a kind of Sir Oracle style, which gently whispers the superiority of "our experiments" over others, and which would place them yet more prominently before the eyes of the world, could we only get the opportunity, and as though our Author's greatness would peep through the veil with which he has invested himself, in spite of his own efforts to prevent it.

Our Author asserts that he can find no written reference to my employment of opium in promoting the growth of granulations since the publication of my pamphlet. That is a somewhat startling assertion, seeing that ample reference to the principle which I had promulgated is to be found in the excellent writings of two leading members of the London Hospital School, and, I presume, Mr. Critchett's own instructors in medicine, if he ever had any. Mr. Critchett has obviously not taken pains to acquire a knowledge of the literature of the subject; but, like some other authors, writes first, and either reads afterwards, or, as in the present instance, does not read at all. Now, these books are accessible to every reader, from the student to the "lecturer" upwards, works of daily reference throughout the Profession, *written from his own hospital, and by two of his own colleagues*; for, as he talks with a flourish about his instruction to the pupils, I presume he has some appointment to the school.

Shall I put down this small breach of faith to Mr. Critchett's want of candour or to his want of observation?

The challenge is a device equally stale and puerile. Why should I, who have thoroughly trodden this ground, a dozen years ago, enter the lists in competition with so formidable a champion as Mr. Critchett? Such contention will hardly serve the cause of truth, notwithstanding the opinion of our Author to the contrary; and, as for credit, pah! "le jeu ne vaut pas la chandelle."

No, Mr. Critchett; the challenge is respectfully, though firmly declined, as they have it in weightier matters.

Mr. Critchett affects surprise (it must be mere affectation) that I would condescend to notice his attack on me. I beg to tell Mr. Critchett, once for all, that I object to all indirect modes of obtaining notoriety; that modesty is a becoming habit for a young man and a young Author.

I did not object to the *thing*, but to the *manner* of the thing. I say, the tone of Mr. Critchett's comments on my principle was offensive to the established courtesy due from one known medical man to another; and I never will cease to contend against professional vulgarisms, believing them to be more hateful and more injurious to the morals of the Medical Profession than is Quackery itself. And so, Sir, I conclude my correspondence with you on the subject of Mr. Critchett, his claims to confidence as an Author, and his Book on Ulcers,

I remain, Sir, your very obedient servant,

F. C. SKEY.

CASE OF STRICTURE, WITH PROFUSE DISCHARGE FROM THE URETHRA.

[To the Editor of the Medical Times.]

SIR,—Is the following case sufficiently interesting and instructive to permit its publicity in the *Medical Times*?

Yours obediently,

HENRY SMITH.

13, Caroline-street, Bedford-square.

I was consulted, about three months ago, by a gentleman from Suffolk, under the following circumstances:—

He had a profuse discharge, from his urethra, of muco-purulent fluid, exactly like that of gonorrhœa. It troubled him excessively, and he wished to get rid of it. He had had gonorrhœa several times, and about two years ago he was treated for stricture by a surgeon, and, apparently, with success, after more than twelve months' irregular attendance; at the end of which period he married. A discharge, however, occurred now and then, sometimes being better and sometimes worse. He again applied to his surgeon, who told him that he had gonorrhœa, and that he must take copaiba. He explained to the surgeon, that he had married a virtuous woman, and that he had had no connexion with any one else, and that he must be mistaken. This did not change his adviser's opinion, and he prescribed copaiba. The patient would not take it, and the discharge diminished, and went away of itself.

On the least excitement, however, it returned; the firm and, as he thought, erroneous opinion of his medical attendant had offended him, and he was recommended to me.

He related the previous circumstances, and showed me the discharge, which was profuse, and so like to that of gonorrhœa, that I almost involuntarily exclaimed, "I could swear you had a gonorrhœa." At the same time, having the advantage of hearing his former history, I suspected he might have a stricture remaining. I requested permission to examine the urethra, and, on doing so, I discovered two irritable

strictures. I told him that this was the cause of the discharge persisting, and that it was necessary for him to come to London every week, to have the bougie passed. I, at the same time, desired him to refrain as much as possible from sexual connexion, and from all other species of excitement.

I need not enumerate the particulars of this case, which was troublesome to treat,—for the urethra was so excessively irritable, that, about three weeks after this, I could only introduce, with some trouble, a No. 4 bougie. In a short time, however, a good-sized instrument could be introduced, the discharge diminished, and, at the end of two months, I passed No. 12 bougie; all discharge had ceased. He had latterly used a weak solution of acetate of zinc, in order to diminish the irritability of the urethra, and hasten the cure.

I advised him to return to me in another month, in order that I might ascertain if the cure was satisfactory. He visited me last week. The urethra admitted No. 12 bougie, and the discharge had never returned.

The points of interest in this case are obvious; it particularly indicates how careful the surgeon should be in giving a decided opinion respecting the nature of a discharge, when the patient is a married man, and denies having placed himself in a position to get infection. It is true, that the surgeon is frequently wilfully imposed upon by his patient; at the same time, an educated and sensible man, if he have any confidence in his medical attendant, will generally tell the truth.

I am by no means surprised that the discharge in this instance was taken for and treated as gonorrhœa, for the similarity was so great that it was almost impossible to give any other opinion; for although it frequently happens that a thin, gleety discharge is produced by a stricture, one of a purulent, or muco-purulent character, exactly like that of a common clap, is rare as an effect of this altered condition of the urethral canal. This case strikingly shows the necessity of examining the urethra with an instrument, if a discharge persists for a length of time, and resists ordinary remedies; for in many such cases the discharge is kept up by the stricture, and unless this be overcome, no permanent cure can be expected to result from remedies by the mouth or by injections; but as soon as the obstruction is fully overcome, the running, whether it comes from the urethra or neck of the bladder, will readily give way. As an instance of the dependence of the discharge upon a stricture, and its rapid departure as soon as this has been treated, M. Leroy d'Etiolles mentions, in his work on stricture, a case of a gentleman suffering under two bad strictures. Here there was such a profuse discharge of thick, mucus-like, false membrane, that the unfortunate patient almost lived upon a perforated chair. This lasted for a year, when the stricture was discovered, and treated properly; and in eight days the discharge ceased, and since ten years has not returned.

ICE IN THE TREATMENT OF CHOLERA.

[To the Editor of the Medical Times.]

SIR,—I was summoned at eleven, a.m., on Sunday morning, July 15th, to a young lady, aged 17, presenting the usual premonitory symptoms of Asiatic cholera, which had continued for about two hours. Her pulse was under 60, and scarcely perceptible; surface cold, countenance pale and anxious, with dark areola round the lids; vomiting and purging incessant; with cramps, and great prostration. The attack was quite sudden, and no cause could be assigned, nor had any case, that I could learn, occurred previously in the neighbourhood. I ordered her at once to bed, first immersing the feet in hot water, with mustard, and fomentations to be kept constantly applied to the abdomen; also, the following mixture to be given:—℞ Mist. Cret., Camph., aa. ℥ij.; sod. bicarb., ℈i.; acid. hydrocyani., ♏. vj. Table-spoonful every half hour, till the vomiting and purging should diminish; to allay the thirst with ice, in small quantities, used frequently. Saw her again two hours after, when she appeared feverish, but with a faint degree of moisture on the skin; vomiting and purging much less, and pain greatly abated. Had taken the mixture thrice. I told her to continue the mixture at intervals of two hours, unless the symptoms again increased, and the fomentations till full perspiration appeared; ice or rice water (cold) to be drank occasionally, as required. In the evening, I found she had perspired freely, and otherwise progressed favourably. Ordered her to discontinue the remedies except cold drinks. Next morning, I found the patient entirely free from the distressing symptoms, and she had passed a good night. To take arrow-root and boiled rice, and continue cold drinks, with keeping her bed. Tuesday, the young lady was convalescent. This communication I thought, perhaps, admissible, as adding a mite to the very many modes of treatment proposed in cholera, and showing possibly how simple remedies, in the primary stage may, if adopted *instanter*, ward off the succeeding, in the greater proportion of cases, fatal symptoms. A happy result can rarely be anticipated in hospital practice from the length of time which must elapse from the commencement of the attack till the patient is fairly taken in hand, when each Practitioner endeavours to combat the then presenting symptoms with such means as his judgment dictates. In cases of diarrhœa, with or without vomiting, I have found ice most grateful to the patient, and serviceable in arresting the irritation and discharge. I was induced to essay this mode from learning its beneficial effects in cholera during the scourge in Paris of 1832, and subsequently in New York, while residing there.

I am, &c.,

J. G. WESTMACOTT, M.D., M.R.C.S., Edin.

6, Porteus-road, Maida-hill, July 24, 1849.

COTYLEDON UMBILICUS.

[To the Editor of the Medical Times.]

SIR,—My attention having been directed to an advertisement in your advertising sheet of the 2nd of June, relative to an extract of cotyledon umbilicus, prepared by Mr. Randall, of Southampton, and said to have been first employed in medical practice by Dr. Joseph Bullar, which is calculated to produce an erroneous impression, I think it due to myself to correct the error which it is likely to occasion.

The cotyledon umbilicus was first used in medical practice by myself, and that too many years before Dr. Bullar ever employed it; and he, moreover, derived all his information originally and directly from me. It is true, that this particular preparation was first employed by Dr. Bullar; but the obvious meaning of the advertisement is, that the medicine altogether originated with that gentleman.

I beg to state, that I believe the error to be unintentional.

I am, Sir, your obedient servant,

THOMAS SALTER.

Poole, July 10, 1849.

NITRATE OF SILVER IN QUINSY.

[To the Editor of the Medical Times.]

SIR,—In a letter from Mr. J. B. Brown, of Haverfordwest, (inserted in the *Medical Times* of the 21st July, 1849,) respecting the valuable use of the argent. nit. in quinsy, I can fully bear him out from my own practice. I have frequently used it with certain success, by its application at the first onset of the disease, and use it in a much similar manner as Mr. Brown. I generally apply it a little below the inflamed surface, which prevents it spreading further. It should be applied pretty freely at first, when you generally find you need no second application; but should it require it, it ought not before eight or ten hours has elapsed from the first application, as Mr. Brown states. I am sure no one will regret its use if they only give it a trial, and I have no doubt they will not often be disappointed, (if ever,) if properly applied; and as we have such a powerful agent in arresting so frequent and painful a disease, it behoves all Medical Practitioners to make the trial; for, as the old adage says, the proof of the pudding is in the eating. I have tried leeches, gargles, poultices, and what not, (also says Mr. Brown,) but upon an average could not prevent suppuration; perhaps that may be partly owing to patients being too late in applying to you; but at the commencing of the attack, nitrate of silver for me.

I generally give six drachms of the sulphate of magnesia in inf. rosæ comp., previous to applying the caustic.

Should you think this worth insertion, you will oblige yours most obediently,

R. M. B.

Ulverston, July 24th, 1849.

UNIVERSITY DEGREES.

[To the Editor of the Medical Times.]

SIR,—I see with regret your trust in the integrity of the motives of your correspondents has been abused, and made subservient, under assumed names, to objects at variance with your intentions to inculcate legitimate discussion and advance Medical science.

In your last Number of the *Medical Times* an abusive tirade against Edinburgh degrees is indulged in from the pen of a Practitioner, who obviously knows nothing of the comparative advantages, or otherwise, of the several Universities, and whose object is merely to advertise himself and the school in which he has studied. The Graduates of Edinburgh here having obtained a status and consideration which he has aspired to without success, and, not having been able to raise himself to their level, he is endeavouring to bring them down to his. This is no fancy. No one of his colleagues who has read the letter in question, that does not feel assured of the authorship, which is in keeping, besides, with an endeavour for a long time, by various means, to carry out this very uncandid and illiberal object.

VERITAS.

July 23, 1849.

P.S.—The address is intentionally omitted, lest by possibility there should be an error in identity, which this appeal will put to the proof, and which no man with honesty of purpose can decline.

NEW INSTRUMENT FOR DISSOLVING STONE IN THE BLADDER.

[To the Editor of the Medical Times.]

SIR,—It has been said, that he who makes *two* blades of grass to grow where *one* only grew before is a benefactor of his species. By a parity of reasoning, the individual who, by his perseverance and skill, shall succeed in alleviating the sufferings of mankind, must thereby establish a claim upon the attention and aid of those whose privilege it is to lead and form the opinions of their fellow-men.

Under the influence of these considerations, I will, with your permission, lay before your readers a description of an instrument which has long occupied my time and attention, and which may prove of signal service to some, and I trust, not altogether uninteresting to all.

The instrument to which I allude is for the purpose of dissolving stone in the bladder without injuring the coats thereof, which I accomplish by means of the following simple contrivance:—

A pump so constructed as to inject and eject at one stroke, connected with which is a pipe of a bougie shape, containing two separate passages, which pipe can be passed into the bladder, the fluid used being made to pass in and out of the same by one stroke of the pump, so that it cannot injure the coats of the bladder, but only operate upon and dissolve the stone with which the solution is brought into direct contact, and thus bringing away portions of the stone with the fluid at every stroke of the pump.

The operation may be repeated at intervals until the whole of the stone be removed.

WILLIAM M'GURY.

119, Bunhill-row, Finsbury.

DRY CUPPING IN INTERMITTENTS BY DR. GONDRET OF PARIS.

[To the Editor of the Medical Times.]

SIR,—It was my intention to have sent you some remarks upon this subject in the month of January last, but other avocations prevented me. Seeing in your number of last week another notice of Dr. Gondret and of his dry-cupping, I presume to obtrude upon you the following observations, and I feel myself the more at liberty to do so having for some time desisted from practice, or rather from the taking of fees, and am therefore free from the suspicion of any interested motive in now addressing you.

About seven years since I resumed the practice of my Profession, after having abandoned it for several years. From that period I have used dry-cupping, not only in the treatment of *intermittent fever*, but in many cases to which other names are given, such as gout, rheumatism, asthma, dropsy, neuralgia, epilepsy, apoplexy, &c. I have no doubt of, and my experience confirms, the success which must have attended Dr. Gondret's plan of treatment, although his mode of applying the dry-cupping differs from that which I adopted and uniformly practised. Dr. Gondret uses several glasses, whereas I generally use but one. I produce the required vacuum by the combustion of a few drops of any strong spirit placed in the glass. Instead, however, of allowing the glass to remain stationary on the patient, I sweep it down the back, over the abdomen, or other parts of the body, with a smart, quick movement, and I repeat the operation as often as necessary, which altogether does not occupy above a few minutes. I am led to conclude that this plan is in every way more convenient, less painful, and di[illegible]tient, and much more powerful [illegible] cutting short the

paroxysm of intermittent fever *in whatever shape it may present itself.*

This mode of treatment, like everything new, elicited any but friendly and liberal remarks from my professional neighbours, who honoured me with the *sobriquet* of "the *dry-cupper.*" Their sneers, however, did not prevent me from pursuing a mode of treatment which every day's experience taught me was most valuable and powerful. Like all the other appliances of our uncertain Profession, its effects for good or evil cannot *positively* be relied on, for in a few instances I have failed to obtain the beneficial effects which it had produced in others of an apparently similar character and nature. I have never, however, in my own practice, experienced any *bad* effects from its application, nor have I heard of any in the practise of others. Its application, therefore, is not attended with the usual risks of other attempted remedies, *all* of which, even those best known for their effects, are more or less uncertain.

The following cases are hastily selected by memory from some thousands. If I were to refer to my memoranda, I could select many of a more extraordinary character, and these with names and addresses shall be furnished with other particulars, if called for.

I am, Sir, very obediently yours,
G. W. BLANCH, M.R.C.S. Ed.
3, Albion-place, Blackfriars-road, July, 1849.

Mr. Bartlett, Builder, Loughborough-road, Brixton.—About 60 years of age. Had been afflicted from his youth with an affection of the chest. For twenty years had been decidedly asthmatic, and unable to lie down in bed, or sleep longer than two hours at a time. When he came to consult me, the weather was very inclement, and he was evidently in great suffering, and almost asphyxiated. He described the sensation at his chest to be as if a burning cord was being tied tightly round him. I applied the cupping glass all over the abdomen with instant relief. He walked home with perfect ease, and slept without disturbance from nine o'clock till seven next morning, and was able to lie in bed in the ordinary position. The cupping was not required to be repeated, but I put him under a course of prussic acid, morphine, and alkalines. He was able to attend to his business, during the following winter, in the severest weather, and could walk at the rate of several miles an hour with perfect freedom.

Mr. Bartlett, Jun.—By exposure to weather, was seized with an acute attack of pneumonia. The dry cupping was freely applied to the abdomen and between the shoulders. The relief was instantaneous, and, with scarcely a dose of medicine, he was next day enabled to resume his ordinary avocations.

Mr. David Meffiss, Merchant, New York, U.S.—Had for several years been subject, during the summer, to attacks of ague, which the treatment pursued had failed to arrest. He came home to England, and put himself under my treatment. I refrained from giving him any medicine, but waited until an attack came on. This happened in about two weeks after I first saw him, and, before I could get to his residence, he had merged from the cold into the hot stage. I immediately applied the cupping glass to the abdomen and down the spine. The attack was immediately cut short, and, with the use of prussic acid and lime-water, he has never had a relapse. He returned to New York, but has visited this country several times since on his business affairs, and, when I last saw him, he continued free from his troublesome attacks.

Mr. Hickling, Farmer, near Crowland, Peterborough, Lincolnshire.—Aged about 50. For nearly twenty years, had been afflicted with neuralgia of the occiput, nape of neck, extending to both shoulders, and to one of the elbows. He had consulted a number of medical men, both in town and country, but without the slightest benefit. He was subject daily to attacks, and, when he came to consult me, was then labouring under one. The cupping glass to the stomach and over the parts affected, relieved him instantly, and there was no relapse; and, with the use of zinc emetics occasionally, and after a short course of calomel, morphine, and strychine, he, for some three years, to my knowledge, continued free from his attacks, and in restored health.

Mr. Parkinson, Cattle-salesman, Smithfield-market.—This gentleman had an attack of rheumatism of the shoulder-blade, by which, for three months, he had been unable to touch the back of his head with the hand of the affected side, or to put on or take off his coat without assistance. Meeting him casually, I offered to endeavour to relieve him. The application of the glass over the shoulder was followed by the entire freedom from pain, and the complete restoration of the movement of the extremity. I have subsequently attended this gentleman for another illness, but he has had no relapse of the rheumatism.

Mr. Brokhes, Plumber, &c., Upper Kennington-lane.—Aged about 45. Was with difficulty able to walk to my house to consult me. He was labouring under all the symptoms of acute hepatitis. The cupping-glass to the abdomen immediately relieved him. This was followed by a few doses of calomel and antimony. He returned to his work in less than forty-eight hours.

Mr. Bennett, aged 43, Corn Merchant, Belvidere-road, and —— Mills, Bushey Park, had, for upwards of two years been in a declining state of health; cough, dyspnœa, and palpitation supervened, and then ascites and anasarca. When called upon to attend him he had for many weeks been unable to walk or lie down in bed, and his body clothes had had to be enlarged upwards of twelve inches. He had been under the treatment of two general practitioners of the neighbourhood, assisted by the consultations of a now deceased President of the College of Surgeons. The treatment pursued seemed to have been principally powerful drastic purges, with occasional blisters, leeches, and sinapisms. It had been proposed, as a last chance, to tap him. At my first visit I applied the cupping-glass in the usual way, over the abdominal parieties and also down the back and lumbar region. The result was, that he slept more than usual that night and in a more recumbent position. The cupping was repeated every other day, and I administered in his bed-room, twice a week, a powerful hot-air bath, by a simple and easy method which ought to be more generally known and practised, and the rest of his treatment consisted of ammonia, liq. potassæ and iodide of potass in a mucilaginous mixture. In the course of a fortnight he was able to resume his ordinary clothing, and to walk from his residence Mark-lane and back on market days. He continued to improve in appetite and strength and continues comparatively well and of ruddy healthy appearance. On two occasions, after fatigue and exposure, he came to me complaining of a sense of tightness about the chest. On both these occasions the usual application of the cupping-glass to the abdomen was sufficient and removed his symptoms without further trouble. I omitted, in its proper place, to mention, that my patient, during the first two weeks of my treatment, lost upwards of forty pounds in weight, but, at the same time, increased daily in strength and physical power.

IMPORTANT TO DRUGGISTS AND MEDICAL MEN.

GRIFFITHS v. WALFORD.

A case of some importance to the Medical Profession was tried a few days since before Mr. Bullock, in the Guildhall County Court. The plaintiff, a Mr. Griffiths, of Wolverhampton, brought an action for damages and compensation against Mr. Walford, of the firm of Lunn and Walford, 149, Aldersgate-street, alleging that, being taken ill while in London, he applied to Mr. Walford for a dose of Sir James Murray's fluid magnesia, which he was in the habit of taking to allay irritation in the stomach, and for a four-grain calomel pill. Mr. Walford administered to him a dose of Epsom salts, whereupon he expressed himself very angrily on the subject, and refused to take any more medicine of Mr. Walford's making. In consequence of the dose of Epsom salts, to which medicine he had a great aversion, as tending to excite, not allay irritation in the stomach, he was laid up for that night and the next day, and detained in London from his business at Wolverhampton. The plaintiff, who acted as his own counsel, said that he did not seek for damages, but to enforce, by the verdict of a jury, upon the attention of medical men and druggists, the principle, so important to the public, that if he or any one went into a druggist's shop, and called for some particular medicine, that druggist—or surgeon in attendance in his shop—should not be at liberty to substitute another, either because he had not got the medicine asked for, or did not choose to sell it; or desired to sell something else by which he made a larger profit; or had the presumption or the vanity to think he knew better than his customer what was good for him.

On the part of the defendant, it was argued by his counsel, Mr. Mellor, that the plaintiff had applied to Mr. Walford for advice, and that were it possible for him to obtain a verdict, no Medical man, for the future, would be safe in prescribing for a patient. He called Mr. Lloyd, Surgeon, of Aldersgate-street, who spoke as to the efficacy of bicarbonate of magnesia, the mixture which he understood, Mr. Walford had given to Mr. Griffiths, and explained that although sulphate of magnesia entered into its composition, its action was neutralised.

"Mr. Walford, of 149, Aldersgate-street, stated that he was a partner in the firm of Lunn and Walford, Mr. Lunn not being his partner as a surgeon, but simply as a chemist and druggist. He is himself a surgeon; Mr. Lunn only makes the preparations. He recollected the plaintiff coming to his shop. He was out at the time, and just returning from visiting a patient, when he met Mr. Griffiths coming out of the shop. He re-entered with him. The apprentice said, that the gentleman wanted some advice. Mr. Griffiths complained of flatulency and heartburn, and said, the mutton and turnips had disagreed with him. He had not been drinking anything. He looked at his tongue, and sent for the bottle containing a mixture of bicarbonate of magnesia. While pouring this out, Mr. Griffiths said he should like fluid magnesia. He replied, he would give him something quite as good. Mr. Griffiths then swallowed the dose; but no sooner had he done so than he pulled a wry face and angrily exclaimed, 'You have given me Epsom Salts, which is wrong.' He replied, 'I have given you something quite as good as what you asked for, and I will not be dictated to by my patients.' He made a rule of not telling his patients what he gave them; as otherwise, on other occasions, they might doctor themselves, and do mischief by an injudicious use of proper medicines on improper occasions. That was the common sense of the mystery of medicine. Mr. Griffiths was very angry, and in an excited manner, said, he did not care for him, to which he replied, that he did not care for Mr. Grifiths, and took his money and left him.

"Cross-examined by Mr. Griffiths.—The mixture was not Epsom Salts, but was composed of bicarbonate of potass and sulphate of magnesia; sulphate of magnesia was Epsom salts, but they became neutralised in that mixture, which then became bicarbonate of magnesia. He could not swear that Mr. Griffiths did not ask him for the fluid magnesia, but distinctly remembered his asking for a calomel pill; thought Mr. Griffiths asked his advice. He complained of headache, flatulency, and heartburn. He could not say whether they had Murray's fluid magnesia on the premises at the time. Epsom salts was not fluid magnesia. He could not remember the name of the patient from visiting whom he was just returning when he found Mr. Griffiths in the shop. Remembered Mr. Griffiths mentioned fluid magnesia, while he had the bottle of mixture in his hand and was pouring it out; will not swear that Mr. Griffiths did not ask for Murray's fluid magnesia. Mr. Griffiths said, 'You shall not make the pill for me; you have given me wrong.'

"Alexander Jackson stated, that he was the apprentice of Messrs. Lunn and Walford; he remembered the plaintiff coming to the shop, and thinks he said he wanted some advice. He remembered the plaintiff saying after he had taken the dose, 'I wish you had given me what I asked for;' and also remembered that he said, 'I won't have the pill; you have not given me what I asked for.' He cannot swear that he remembered hearing plaintiff ask for Murray's fluid magnesia, but will not swear that he did not ask for it.

"Mr. Lunn, of the firm of Lunn and Walford, said, that he was a chemist and druggist, and in partnership with Mr. Walford. They had Sir James Murray's fluid magnesia in stock on the 1st of April. They obtained it from Mr. Edwards, St. Paul's Churchyard. He does not sell much of it, as he generally sells his own preparations, which pay him better.

"Cross-examined by Mr. Griffiths.—Begged distinctly to state to the Court that he did not profess a knowledge of anatomy, or the practice of physic; was not a surgeon, and did not wish to be examined as one. He was a chemist.—Mr. Griffiths: Very well, Mr. Lunn, we will examine *you* as a chemist then. [The discussion as to the elements of Epsom Salts, and the true properties of sulphates, carbonates, and bicarbonates of magnesia, here became so animated and exciting between the various medical witnesses, and Mr. Lunn and Mr. Griffiths, both of them operative chemists, that the judge, the jury, the court, and even the cause itself, seemed to be forgotten, and we might have fancied ourselves present at a scientific *reunion*; when, on a sudden, a very *naive* offer, made by Mr. Griffiths in the excitement of the discussion, that the jury should test the two by taking a dose of the Epsom Salts and a dose of

the fluid magnesia, convulsed the jury with horror, and the court with laughter. This trial by ordeal, was, it is needless to say, declined with great energy by the gentlemen of the jury, and the examination proceeded.] Mr. Griffiths: Mr. Lunn, as an operative chemist, do you know a bottle of Murray's fluid magnesia when you see it? Yes.—Do you keep it in your shop? I do.—Do you sell much of it? No. How is this? I sell my own preparations, which pay me much better.—Now, Sir, will you tell the jury whether Epsom Salts are Fluid Magnesia? They are not.—Is Murray's Fluid Magnesia Epsom Salts? Certainly not.—Do you make all your own preparations? No.—What do you make? Those preparations that pay me best.—That I was aware of, Sir, but that is no answer to my question. Do you make the preparations of opium, morphine, and so on? No.—Extracts? No.—Plasters? No.—Paregoric and syrup of rhubarb, I suppose you do make? Yes.—Pray, Mr. Lunn, are you a member of the Pharmaceutical Society? I am not.—Not a member of the Pharmaceutical Society: oh, indeed! I shall not examine you any further then.

Mr. Griffiths, in replying to the defence, said, that, as to this question being so important for the future safety of Medical men in prescribing, how much more important was it to their patients.

"What safety is there, to any of us," said he, "that a prescription, obtained at a great expense, and in the crisis, it may be, of some fatal disorder,—from some eminent Physician, requiring the nicest discrimination and accuracy in its preparation—and there are medicines, gentlemen, as the records of coroners' inquests too fatally make known to us,—in which the turn of a scale, or the measuring of a half drop make the difference between health and death—what security have we, I ask you, if such as I now complain of be the practice of druggists? What security have we—the ignorant, confiding public—mystified by the Latin of the prescription, and bamboozled by the mysterious importance of the surgeon-druggist, that he will not make up this carefully-obtained prescription, on which the life of the bread-gainer of a large family may depend, totally different from the purpose and intention of the able Physician who wrote it—and administer to us some drastic sulphate, or bitter nauseating salt like this, instead of a tasteless, inodorous, and innocently refreshing medicine, like Murray's fluid magnesia, or any other proper ingredient, legibly written in our prescription?"

Mr. Griffiths then went on to say,

"That an attempt had been made by the doctors to get out of the difficulty by suggesting—they did not venture to swear it—that he had asked for advice. If he asked Mr. Walford for advice, why did he ask him for a calomel pill? When you ask a doctor's advice, do you tell him what to give you? If he had asked his advice, and stood there to take the medicine as recommended, how came he to be so angry about the Epsom salts? Could he have shown so much feeling, if he had taken them under Mr. Walford's advice? What right would he have had to say—'You are wrong!' Is that the speech of a patient to a doctor whose advice he is seeking? Is it not rather the reproach of a man, who has asked for one thing and finds himself aggrieved by the substitution of another? Away then, at once, with this flimsy pretence of his having asked for advice. He was himself a chemist and druggist, and went into the shop of Messrs. Lunn and Walford to get the medicine—Murray's Fluid Magnesia—which he was in the habit of taking. Mr. Walford had chosen, from carelessness, or design, or from the habit of always *giving* Mr. Lunn's own preparations, (a very natural reason,) to administer him what he did not want. He did so on his own responsibility, and he must take the consequences. He (plaintiff) would now repeat what he had before said, that he had no personal feeling in the matter, and no desire for vindictive damages. It was the principle in question for which he stood out,—that the druggist should sell to his customer the article for which the customer asked him, and not substitute, at his pleasure, another medicine, because more convenient or more profitable to himself. The public safety required that this rule should be rigidly enforced amongst medical men. 'There is no profession,' said Mr. Griffiths, 'in which we are called upon to place so much implicit faith and confidence as the medical. Why, almost more than one-half of the secret of success in medicine is the confidence—the reliance of the patient in the physician. And what defence have we—what safeguard? If one lawyer deceive us we can go to another: if one clergyman attempt to lead us from the right path, we have the Holy Book, where we may track his wanderings and map our own way back again to the right course; but the doctor! he first kills you, and *then* leaves you to your remedy. (Great laughter.) In your hands, gentlemen of the jury, I now leave this important question, trusting that you will bring your common sense to bear upon it, and return a verdict which will teach the Medical Profession not to tamper at their will with the health of those who place implicit reliance on their supposed good faith.

"His Honour observed that there were several points in this remarkable and ably argued case, which he must submit to the consideration of the jury. First, whether the plaintiff asked the defendant for advice. Secondly, whether he asked for Fluid Magnesia and received Epsom Salts. Thirdly, whether he received not Epsom salts, but something equivalent. Fourthly, whether this was done through gross ignorance or negligence on the part of the defendant—because, if not, the plaintiff would not be entitled to recover. Fifthly, whether he had waived the medicine he had called for by tacitly taking what was given him in place of it. These points, and the question of amount of damages he must leave to their consideration.

"The Jury, after some discussion among themselves, retired to consider their verdict.

"In the meantime, the Judge intimated his wish to taste some of Sir James Murray's Fluid Magnesia, which, combined with the Acid Syrup, also of Sir James's preparation, appeared to make a cooling and refreshing effervescing beverage. Mr. Griffiths politely supplied His Honour with a glass of the mixture, which he pronounced, *ex cathedrâ*, to be 'delicious.' The opposing counsel and solicitor also requested a "refresher," and the whole Court, as far as the bottle would go, proceeded to try Murray's Fluid Magnesia; after which, they pronounced a unanimous verdict in its favour. At this moment the Jury returned to their box, after an absence of half an hour, and returned a verdict for the plaintiff.

"The trial lasted five hours, and excited an intense interest."

DEATH OF DR. JOHN REID.

Died, at St. Andrew's, Fife, on the 30th of July, 1849, John Reid, M.D., Professor of Anatomy and Medicine in the University of St. Andrew's. It is with great regret that we make this announcement. In Dr. Reid's death the Profession has lost one of its brightest ornaments, and those who have watched the modern progress of physiology will perceive, that one of the most philanthropic minds of the present generation has passed away.

It has for nearly two years been a source of deep grief and anxiety to all Dr. Reid's friends that he seemingly bore upon him the indications of the fatal malady which we believe caused his death. Prior to this date even, there was reason to dread the presence of cancer in the tongue, and too surely did that dream become developed. Notwithstanding the anxious solicitude of his professional friends, the affliction made such inroads upon his health that he had resigned himself to his fate more than twelve months since. At his own earnest request (whilst manfully prepared for the worst, in whatever way it might come,) an operation was performed in the month of August, 1848, which enabled him to rally so greatly, that hopes were entertained that his useful life might still be spared. But the hand of fate was upon him—his restoration to his wonted health—his relief from suffering—were of comparatively short duration. The stealthy disease made progress in the neck and throat, and finally laid in death one of the most manly frames we ever saw.

Dr. Reid's career, though brief, (he was, we think, in his 41st year,) has been eminently brilliant in the path which he chose. Early in life he devoted much attention to the study of the healthy anatomy of the human frame; and his sound elementary knowledge, in this department, doubtless gave great precision and character to his subsequent labours in pathology and physiology. Soon after obtaining his degree of M.D., in the University of Edinburgh, he was appointed Practical Pathologist to the Royal Infirmary of that city, and, whilst ably discharging the laborious duties of that important office, he was also engaged in some of those interesting physiological researches which so greatly contributed to his reputation. It was then that he made his great "Experimental Investigations into the Functions of the Eighth Pair of Nerves, or the Glossopharyngeal, Pneumogastric, and Spinal Accessory," the results of which were intimated to the British Scientific Association at the meetings of 1847 and 1848, and subsequently published in detail in the *Edinburgh Medical and Surgical Journal*, for January, 1848, and April, 1849.

Soon afterwards, he received the appointment of Chandos Professor of Anatomy and Medicine in the University of St. Andrew's, and by his presence there, as, also, by the discharge of his duties in that time honoured institution, he contributed much to raise the character of the medical degree, which now emanates in increased frequency from that ancient seat of learning.

Dr. Reid's various and numerous scientific papers were published, at first, as communications and contributions to the Journals of the day; and, on that account, many of them were in a manner overlooked amidst the vast amount of talent now devoted to this department of scientific literature. Happily for our profession, Dr. Reid was induced to reprint these papers, and publish them in a connected form, and it is not long since we had the gratifying task of reviewing the volume which they formed. Had these papers appeared in this shape for the first time, they would, without doubt, have created far greater sensation than that with which the volume was hailed. As it is, the work contains a greater amount of original and well-digested useful matter than any of the size to which we can allude, as the result of one man's labours in modern times. The "Physiological, Anatomical, and Pathological Researches," (a) of John Reid, will long form a standard work of reference to those who follow in the useful course which the Author pursued.

The published works of Dr. Reid speak for the manly vigour of his mind, and we have reason to state, that he bore his sufferings, and anticipated his early death with the greatest moral fortitude. We cannot give a higher proof on this latter point than by stating, that he actively superintended the publication of the volume to which we have referred, under the consciousness that death was fast coming upon him, and amidst sufferings from which he could get temporary relief only by strong narcotic doses. After the joyful hopes encouraged by the partial success of the operation which was performed upon his tongue, were finally damped, and his earthly doom in a manner sealed, he still devoted part of his limited time to the cultivation of science, and June, 1849, published in "The Annals and Magazine of Natural History," a most elaborate account of the Vogmarus Islandicus, which had some time recently been thrown ashore in the Firth of Forth. Whilst thus engaged adding to his earthly reputation, we know that he expressed his satisfaction at the relief which the operation afforded, and, in a communication to one of his oldest friends, he "thanked God that his time on earth had been prolonged, so that he might make greater preparations for that great change to which he looked with Christian resignation."

Dr. Reid possessed many of the national characteristics of his countrymen. His manners were quiet and unassuming. At first glance a stranger might have mistaken his qualities; but soon the broad intellectual forehead, the dark flashing eye, the shrewdness of his observations, showed that he was a person of no ordinary stamp. Among strangers he was quiet, and seemed desirous to escape observation. He was cautious in forming his friendships; but once having done so his sentiments seldom swerved. Among his intimates he was lively and social, "slow to anger," and, withal, so full of the milk of human kindness, that during an intimate friendship of more than twenty years, the writer of this brief notice never once heard an ill-natured expression pass his lips.

Take him for all in all, how rarely do we see a man like John Reid? Peace to his soul! Honour to his memory!

(a) Sutherland and Knox, Edinburgh, 1848.

MEDICAL NEWS.

Apothecaries' Hall.—Names of gentlemen who passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday July 26th, 1849 :—Edward Jackson, Sheffield; Thomas Allen, London; Arthur Octavus Arden, Beverley, Yorkshire; Richard Eaton Rusher, Oxford; William Talbott King, Hackney; Joseph Barton Carter, Beverley, York shire; Charles James Evans, Belper; George Cochrane Millar; John Markwell Todd, New Cross Road, Deptford; Thomas English; John Harrison Robotham, Wilne, Derbyshire.

Royal College of Surgeons.—The following gentlemen, having undergone the necessary examinations for the diploma, were admitted members of the College at the meeting of the Court of Examiners on the 27th inst.:—Messrs. Edward Leopard Neville, Hounslow, Middlesex; Owen William George, Plascrwn, Pembrokeshire; William Percy Pickard Mackesy, Waterford; Edward Philip Leigh, Jamaica; Edward John Vivian, Guildford-street, Russell-square; Arthur Rudge, Pakenham, Norfolk; William Aston Lewis, Manchester; Robert Adamson, Durham; John Harrison Robotham, Wilne, Derbyshire; Joseph Sawyer, Whitehaven, Cumberland; and John Earnshaw, Clithero, Lancashire. And on the 30th ult, Messrs. Charles Mathias Meller, Ecclesfield, near Sheffield; Frederick Bateman, Norwich; Thomas Kiran White, Threecastle County, Kilkenny; Thomas Llewellyn Nash, Dublin; Thomas Wilson, Elverstown, Blessington County, Kildare; David Morgan, Bodwigiad, Breconshire; John Rorie, Plymouth; Charles Augustus West, Consumption Hospital, Brompton; John Wood, Bradford, Yorkshire; Samuel Plumbe, London; and John Cromwell Blackford, Bromsgrove, Worcestershire.

Appointments.—Mr. Edwin Canton, one of the Surgeons of the Royal Westminster Ophthalmic Hospital, has just been elected Surgeon of the Royal Infirmary for Diseases of Children, in the vacancy occasioned by the resignation of Francis Hird, Esq.

Collegiate Prizes.—The Council of the Royal College of Surgeons have just announced the subject of the Collegial anatomical prize for 1851 to be, on the "Functions of the several parts of the large Intestines in Animals of the class Mammalia." The prize is of the value of fifty guineas. The Jacksonian prize subject is, "Neuralgia, its various Forms, Pathology, and Treatment," and is of the value of twenty guineas. Additional information may be obtained on reference to our advertisement columns.

War Office, July 27.—1st. Regiment of Foot.—Staff Assistant-Surgeon Edward Burrowes Sinclair to be Assistant-Surgeon, vice Hoskin, who exchanges. Hospital Staff. — Assistant-Surgeon William Thomas Hoskin, M.D., from the 1st Foot, to be Assistant-Surgeon to the Forces, vice Sinclair, who exchanges.

Obituary.—At Salisbury, 23rd ult., Richard Brassey Hole, M.D. On the 27th inst., at Stockwell, aged 36, Mr. Benjamin Kealley, of Little Newport-street, Leicester-square, Surgeon.

The Late Mr. Clift.—The sale of the effects of this gentleman commenced yesterday, and concludes this day. It is not generally known, that the lamented deceased carried the homage of his illustrious master to so great an extent, as to purchase, not only everything relating to him, but carried his feelings so far, as to expend every farthing he had in the purchase of the original engraved plate of John Hunter, by Sharp, at the sale of the effects of the latter. In the catalogue we notice several impressions from this plate, for competition; it is taken from Reynolds' picture of Hunter, and is admitted, by the best judges, to be one of the finest, if not the very finest specimen of the art ever executed in this or any other country, and is considered superior to the best efforts even of Raffael, Morghen, or Desnoyers.

Death of Mr. Andrews.—This gentleman expired at his town residence, St. Helen's-place, Bishopsgate-street, on the 28th ultimo, in the 68th year of his age. Mr. John Goldwyer Andrews commenced his study of the Profession at an early age, and, if we mistake not, was an articled student of the late Sir William Blizard, who, however, was never particularly attached to his pupil. Having finished his studies, he passed the College so long ago as the 2nd of September, 1803, and, on the 26th of May, 1827, was elected a member of the Council of the College, in the vacancy occasioned by the resignation of the late Sir Everard Home, Bart., and, on the decease of Mr. R. C. Headington, the President of the College, and his colleague at the London Hospital, he succeeded that gentleman as a member of the Court of Examiners, on the 2nd of March, 1831. On the 9th of July, 1835, he received from his colleagues the highest appointment they could bestow, that of President of the Royal College of Surgeons, an appointment that was a second time conferred on him on the 13th of July, 1843. It does not appear that these appointments were conferred on the deceased for any valuable contribution to the advancement of surgery, or success as a brilliant operator, as we have searched catalogues of libraries, transactions of learned societies, and the medical journals of the day in vain for the results of his experience. As a hospital surgeon, his advancement in the Profession appears to have been due to his good fortune, his early connexion with influential men, and the then prevailing mode of elections to hospital appointments, and collegial distinctions. Now, happily, the day is rapidly passing away in which honours can be secured without pretence to merit; and we hope to see, ere long, those positions of responsibiltiy and dignity held by men who have conferred a benefit on science and on the Profession; but, "*de mortuis nil nisi bonum.*" We understand, that Mr. Andrews was a patron of the fine arts, and had made, at his magnificent country seat, Glanbrydan, Carmarthenshire, South Wales, a collection of paintings, variously estimated of the value of from 15,000*l.* to 20,000*l.* By the death of this gentleman, a seat at the Council and Court of Examiners of the Royal College of Surgeons is rendered vacant, as also the surgeoncy of the London Hospital. The immediate cause of the death of Mr. Andrews was rupture of the aorta. Mr. Andrews possessed considerable landed property surrounding his country seat in Wales, in the improvement of which he took great interest.

The Public Health.—Again the return indicates an increase on the excessive mortality of the previous week. The deaths from all causes, which in three previous weeks were respectively 1,070, 1,369, and 1,741, rose in the last to 1,931, a number which is almost double the weekly average, and exceeds that of the former week by nearly 200. To compare these results with the deaths from all causes in four weeks, when influenza was unusually fatal, in the last quarter of 1847, it may be stated, that the mortality at that time increased in the following numbers:—1,086, 1,677, 2,254, 2,416, and in the fifth week continued to decline. The deaths from cholera, which in the three previous weeks were 152, 339, 678, rose in the last to 783, a rate of increase which, it will be observed, is not so great as in the first weeks of th outbreak. But the deaths from diarrhœa (fatal in a great majority of cases to children) and dysentery, which in three previous weeks were 54, 100, and 146, increased in the last to 238, showing a more rapid increase recently than the mortality from the more malignant form of the disease. In the corresponding week of 1848 the deaths from diarrhœa and dysentery amounted to 187, a mortality which is almost as considerable as the return of last week. The total deaths from the three diseases in the present return were therefore 1,021, whilst the weekly average of the season is only 92, a result when compared with the excess of mortality from all causes, which shows that the aggregate deaths from other diseases do not vary much from the usual amount. Small-pox, scarlatina, and typhus, however, are now under the average, especially the first two of these zymotics; measles and whooping-cough have fallen to the average. Cholera was fatal last week to 382 males and 401 females; previous returns showed a majority on the other side. The districts on the south side of the river still form the field on which the disease is most active. The deaths from it, which in this region were in three previous weeks, 93, 192, 443, rose last week to 514. There is a slight decrease in the eastern districts. In the western and northern, comprising Kensington, Chelsea, St. George (Hanover-square), Westminster, St. Martin-in-the-Fields, St. James, Marylebone, Pancras, Islington, Hackney, and Hampstead, the deaths were only 68 against 53 in the preceding week. The districts which show the greatest mortality are Bermondsey, where 64 deaths occurred last week; Newington, where there were 66; St. George (Southwark), where there were 70; and Lambeth, where there were 111. The mean height of the barometer in the week was 29·598. The temperature was generally below the average during the week. The mean was 58o.9.—*From the Registrar-General's Return.*

Presentation of Dr. Birt Davies's Portrait to Queen's College, Birmingham.—The council, professors, and tutors of Queen's College, and upwards of 100 students, partook of a splendid *déjeuner* in the dinner-hall on Friday week, on the occasion of the presentation of the portrait of Dr. Birt Davies to the Institution. The chair was occupied by the Vice-Principal, the Rev. Chancellor Law. Letters expressive of regret at unavoidable absence were received from the Right Hon. the Principal, the Earl Howe, the Lord Bishop of the Diocese, Richard Spooner, Esq., M.P., G. F. Muntz, Esq., M.P., William Scholefield, Esq., M.P., and other gentlemen. At the conclusion of the repast, the Rev. Vice-Principal delivered an appropriate address, in which he eulogised the efforts of Mr. Sands Cox, and others, in founding, establishing, and promoting the best interests of the rising College. To Dr. Birt Davies the Council owed a great weight of obligation, for devoting his time, energies, and talents to the cause of the Institution; and it had now endeavoured to do him honour by presenting his portrait to the College. Professor Birt Davies responded in a feeling and elegant speech, during the delivery of which he was frequently interrupted by the loud plaudits of the company.

The Cholera in America.—A Correspondent of the *Buffalo Express*, writing from St. Louis, July 5, says:—"The city, from a population of nearly 70,000, is now reduced to not over 30,000. Everybody has fled but those too poor to leave, or whose business compelled them to remain. The streets are deserted, except by the hearse and the mournful procession moving to the gloated cemeteries. The blackened ruins, instead of being removed and giving way to new places of business, as they would but for the pestilence, now present a sad spectacle of desolation. Few steam-boats are running, and those go away loaded with the affrighted population, but bring back no passengers. The deaths, as reported for several weeks, have been from 100 to 160 per day, while it is conceded by all who know, that from one quarter to one-third are not reported, so that the actual number of deaths, for some time past, has not been much less than 200 per day—or say 1200 per week—and that, too, in a population of from 30,000 to 35,000. Of course, hearses are constantly to be seen in the streets, and the entire night is spent in burying the dead. It is, however, an indisputable truth, that at least three-fourths of all the mortality is among the foreign population, now arriving or recently arrived from Europe. Every boat from New Orleans brings up from 100 to 500 of these poor creatures, just landed from the steerage of ships, filthy and in every respect prepared to take the disease. They are crowded like swine on the boats, and frequently many are dead before arriving at St. Louis." At New York the rate of mortality was still increasing; and quite a panic had been excited amongst the higher ranks of society. It is observed, that the variations of the atmosphere had been most unusual. In twenty-four hours a difference of 20 degrees was experienced; and whilst the heat of the 15th was the most intense known for ten years, the two days following were precisely the reverse.

MORTALITY TABLE,

(Metropolis.)

For the ... *Saturday, July 28, 1849.*

Causes of Death.	Total	Average of Five Summers
All Causes	1931	1008
Specified Causes ...	1930	1005

TO CORRESPONDENTS.

Last week, we received the following Advertisement, to which, it is hardly necessary to say, we refused admittance —

"To Medical and Surgical Practitioners, &c —A Gentleman, who has served an apprenticeship to an Apothecary, and who holds his indenture, but who has not attended the courses of lectures, from his attention having been absorbed in years of practice, and being threatened by an action from the Apothecaries' Company, has resolved at last to obtain a diploma If it can be procured without much loss of time, would be glad to avail himself of the assistance of any gentleman who could aid to procure the article in question, shall be liberally rewarded

The Advertiser contemplating emigrating the document of any gentleman relinquishing the Profession might answer his object —Address, - -, Liverpool, until called for

Among the numerous tricks adopted to gull the public and hoodwink the profession, this is remarkable, on account of its novelty The gentleman who is so anxious to obtain a diploma without much loss of time has, upon the strength of five years' apprenticeship engaged in the practice of the healing art Doubtless he has ranked amongst those worthies who have performed cures in cases which more legitimate doctors have pronounced incurable. He is evidently a precocious genius for scarcely does he escape from the trammels of apprenticeship than he plunges *in medias res* of medical practice and has his attention so completely absorbed with it that he casts aside the thought of attending lectures or of obtaining a diploma How the sleeping Cerberus of Water lane was roused to attack him we are at a loss to conjecture and it seems that, once awake, no sop which this modern Hercules of medicine could throw was sufficient to lull him again to sleep A diploma must therefore, be obtained but how is this to be done without much loss of time? A genius who had accomplished such wonders in the practice of physic felt himself equally competent to did [illegible] a Medical Corporation There were numbers of diplomaed doctors without patients and who would be glad to dispose of, to them the worthless paper upon advantageous terms A daw in borrowed plumes might perchance be plucked but at least for a season he would pass for a genuine peacock and the deception might never be discovered in a distant colony The resolve is made, the gentleman "absorbed in years of practice" sends an advertisement to the 'Medical Times,' and expects as many applicants as a merchant who advertises for a confidential clerk, who would receive a salary of £1000 a year and have but little to do

We have done what we could to foil such a disgraceful attempt to mislead the Profession and the public We have reason to fear that there are persons, both at home and abroad who practise with borrowed titles and we should rejoice in their exposure and punishment Our Medical Corporations should not only publish annually, a correct list of their members, but should endeavour to ascertain when any of them die in order to erase their names from the lists The friends of deceased medical men should also take care that their diplomas and certificates be not disposed of as waste paper What we want among other things is a proper register of all qualified Medical Practitioners in the three kingdoms

"H S Holborn" will find a letter at our publishers

"Anatomist"—The "*post mortem*" gloves were invented by M Blatin They are made of very thin cautchouc, and do not diminish the sensation of the fingers

"An Apprentice"—The term empiric is derived from the Greek word *εμπειρικος* and was applied originally to a medical practitioner who trusts to experience alone for his knowledge of medicines and diseases, totally discarding all theory and speculation It is now used in a very different sense

"A Surgeon"—We lament in common with our correspondent the great destruction of human life from poisoning by arsenic We fear however that the suggestion of substituting for the mineral when asked for cream of tartar will not prevent the evil We think that arsenic ought not to be sold by retail druggists to casual customers

"A Subscriber Leicester," informs us that he has been much annoyed in prescribing the Ext Tar Tarax, as prepared according to the London Pharmacopœia to find it very frequently inert and wishes us to inform him, if there is a better method of preparing it than that ordered by the College The officinal extract does not possess the virtues of the root By exposure to air during ebullition, a quantity of grape sugar is formed at the expense of the peculiar starch or inulin of the root and a portion of the active principle the product is a preparation without power A very different article, however is obtained by simply crushing the fresh root, diluting with about one gallon of water to the cwt separating the juice by hydraulic pressure, coagulating, filtering and evaporating the clear liquor in vacuo free from atmospheric depreciation Thus prepared, the inspissated juice is firm and transparent, possessing the true flavour of the root, and the medicinal properties of the herb unaltered. The best time for collecting the roots is in November.

"Inquirer"—Arterial blood always contains some carbonic acid; venous blood, oxygen

"Galen"—To obtain a medical degree at Oxford, a residence in some College or Hall is required. We would advise our Correspondent not to trouble himself about such a diploma, as it affords no proof of superior medical education

"G. M T."—There is no chemical change when calomel and pulv. antimonials are mixed

"Medicus"—Amorphous quinine is a much cheaper preparation than the Sulphate

"Scotus"—The Apothecaries' Company will not prosecute a properly educated medical practitioner not possessing its certificate

"Mr Leonard."—We know nothing of the Society referred to

"A Student" should address a letter to the Secretary of the College of Surgeons.

"Miles"—A Member of the Edinburgh College of Surgeons is eligible for an army medical appointment

"A General Practitioner" not being a licentiate of the Apothecaries' Company cannot recover the amount charged for attendance &c, on a medical case

"Dubitans"—Cancrum oris sometimes occurs without any mercury having been given to a child In the case mentioned we should hardly think that so small a quantity of calomel produced such serious consequences The disease is more common after measles, than other eruptive diseases, and it is always connected with a depressed state of the vital powers

"Kappa"—Cinchonine is rather less soluble in water than quinine, and more readily crystallizable than that alkaloid

"M D"—Much consideration is requisite We will give the subject our best attention

"Adolescens"—(1) No Assistant Surgeon in the Navy can be promoted to the rank of surgeon until he has served three years in the former capacity one year of which must be in a ship actually employed at sea (2) We have not heard of any recent notification from the Admiralty in behalf of Navy Assistant Surgeons

"A Retail Chemist" should address his letter to the Board of Stamps Somerset house

"Anglicus"—The School of Physic in Ireland is connected with Trinity College and the King and Queen's College of Physicians The School consists of six professors on the foundation of Sir Patrick Dun The College of Physicians has also established two additional professorships, —midwifery and medical jurisprudence

"M B"—We believe that some poisons are absorbed into the circulation, and being eliminated by the kidneys may be detected in the urine by their chemical or physiological reactions

"An Experimentalist"—Adipocere is probably nothing more than an animal soap with a base of Ammonia or lime the former making being the result of the decomposition of the nitrogenized principles of the body while the fat becomes acidified

"Rusticus"—The Censors and other officers of the College are elected on the 25th of June, when the Harveian oration is delivered

*** "Camberwell"—We do not think the Ergot of Rye exerts any decided influence on the unimpregnated uterus

"Medicus" informs us that the St Andrew's diploma is 3s not £3 more than the Edinburgh

"A Reformer of Abuses" says that the only and legitimate method of putting down quackery is to restore into the hands of the apothecary or chemist his own office,—that of dispenser If this is done, he will not presume to act in the capacity of prescriber nor will he demean himself by supplying the uneducated quack with drugs to cheat the public as it would be injurious to himself and the prescriber

Dr Coppinger will see that his request has been attended to

"W R Hope Jones, Conway"—Communication received

"Dr M Wylie, Glasgow."—A brief abstract of the paper was inserted in the 'Medical Times' in the Column to Correspondents shortly after its receipt The number we cannot exactly name

"Scrutator"—Communication received

Boven County Cork Ireland —1 The French gramme is rather more than 15 grains avoirdupois the decigramme rather more than a grain 2 We are not aware of any formula for the exhibition of the alkaloid

"M D" states that in a girl, at the early age of 5 years and 9 months the catamenial discharge appeared, and has continued with but slight intermissions to the present time She is now 17 years of age, and has grown but little.

"Mr Wm Thomas Pembroke Dock" bears testimony to the utility of Mr Brown's remedy in the treatment of cynanche tonsillaris Our correspondent first used it about twenty years ago in an obstinate case of chronic inflammation of the pharynx, with marked success Since then he has used it extensively in acute and chronic inflammation of those parts with evident benefit In ulceration of the tonsils and preventing suppuration, if early used, he has found it most advantageous.

"Mr Liddle's" letter shall appear next week.

"Dr J Hooper, Buntingford, Herts"—"On Imperforate Anus"—Received

Dr Rigby's valuable paper on Anteversion of the Uterus will appear next week also Dr. Day's interesting communication on the Thermic Treatment of Rheumatism.

ORIGINAL LECTURES.

LECTURES ON THE CHEMISTRY OF THE POISONS; OR, ON PRACTICAL TOXICOLOGY.

SHOWING THE APPLICATIONS OF CHEMISTRY TO THE DISCOVERY OF CRIME.

By H. LETHEBY, M.B., Lond:
Lecturer on Chemistry at the Medical College of the London Hospital.

LECTURE IV.

General remarks on the mineral acids.—Sulphuric Acid — Composition of the several varieties of it, as of the pure acid; Nordhausen-acid, the strongest acid of English commerce; ordinary commercial acid; Graham's acid. Physical properties of oil of vitriol; its density.—Ure's Table of specific gravities; Letheby's ditto; boiling points of the different acids.—Chemical properties of sulphuric acid; its affinity for water, table of temperatures produced by mixing it therewith, action of this acid on litmus; the delicacy of the test; action of the acid on metals; action of it on organic matters, general mode of action thereon; its action on sugar, flour, starch, wood, and linen cloth.—Concluding remarks on its mode of action on vegetable substances.

We will proceed to-day, gentlemen, to the proper business of the course, and commence our work by instituting an inquiry into the physical and chemical characters of the *mineral acids;* under which name I include sulphuric acid, nitric acid, and muriatic acid. These acids are very common articles of trade; for they are largely used, not only for the execution of numerous processes of the arts, but also for a variety of manufacturing and domestic purposes. They are, therefore, accessible to all persons, and may be purchased at any time without exciting suspicion or inquiry. But, for all this, the instances in which the mineral acids have been employed as poisonous agents, are, comparatively speaking, few; and this you will readily understand when you consider that the very powerful acid and styptic taste of these liquids is generally sufficient to prevent them from being used by the secret poisoner: nevertheless, there are a few cases on record, in which persons have made choice of one or other of these acids for the purpose of destroying young children. Occasionally, also, they have been used for suicidal purposes, and not unfrequently they have been swallowed by accident. Moreover, a few years ago the mineral acids were very often employed by the mischievous and ill-disposed for the purpose of staining, or corroding the dress of individuals.

All these circumstances indicate a necessity for your being acquainted with the physical and chemical properties of these liquids, so that you might be enabled, not only to recognise the peculiar effects which are manifested by them, but also to resort to the means whereby the agents themselves may be detected.

SULPHURIC ACID.

The strong solutions of this acid are commonly termed oil of vitriol; and they have received this name on account of their thick oily appearance, and also by reason of the fact that the acid was originally procured by the destructive distillation of green vitriol, or common sulphate of iron: indeed, the process whereby it was at first obtained from this source is still resorted to in many parts of Saxony, as at Goslar, Nordhausen, &c.; and chemists are thus enabled to obtain an acid of greater strength than that which ordinarily occurs in English commerce.

COMPOSITION OF THE SEVERAL VARIETIES OF SULPHURIC ACID.

1. *Pure Anhydrous Sulphuric Acid* is a rare substance;—it consists of one equivalent of sulphur, equal to 16 parts, and three equivalents of oxygen, equal to 24 parts, making an equivalent of sulphuric acid, the combining proportion of which is 40; and the symbol for which is SO_3; or, to represent its composition by per centage numbers, it consists of 40 parts of sulphur and 60 of oxygen.

2. *Oil of Vitriol of Commerce* is composed of this dry acid, and various proportions of water; for example:—

(a) *The Nordhausen, or Saxony Sulphuric Acid,* which is the strongest of all commercial varieties, has a specific gravity of 1900, and it is said to be a compound of two equivalents of dry acid, equal to 80 parts, and one equivalent of water, equal to 9 parts. Its formula, therefore, is $2\,SO^3 + HO$, and it contains about 90 per cent. of anhydrous acid.

(b) *The strongest Acid of English manufacture* has, according to Dr. Ure, a specific gravity of 1845, and it is composed of one equivalent of dry dry acid, equal to 40 parts, and one equivalent of water, equal to 9 parts. Its formula, therefore, is $SO^3 + HO$, and it contains about 82 per cent. of anhydrous acid.

(c) *Ordinary Sulphuric Acid of English Commerce,* is a very variable liquid; that which has a specific gravity of 1843, is presumed to be a compound of four equivalents of dry acid equal to 160 parts, and five equivalents of water, equal to 45 parts. Its formula, therefore, is $4\,SO^3 + 5\,HO$, and it contains about 78 per cent. of anhydrous acid.

(d) *A fourth Acid has been referred to by Professor Graham,* which has a specific gravity of 1780; and it consists of one equivalent of dry acid equal to 40 parts, and two equivalents of water equal to 18 parts. Its formulæ, therefore, is $SO^3 + 2\,HO$, and it contains about 81 per cent. of real acid.

(e) Lastly, an acid has been mentioned by the same authority which has a specific gravity of 1682, and which consists of one equivalent of dry acid, equal to 40 parts, and three equivalents of water, equal to 27 parts. Its formula, therefore, is $SO^3 + 3\,HO$, and it contains about 60 per cent. of anhydrous acid.

All of these varieties of commercial acid are generally regarded as definite compounds of dry sulphuric acid and water, while the other and more varying specimens of oil of vitriol are considered to be accidental mixtures of these liquids. For my part, however, I am not disposed to view the subject in such a light; but am tempted rather to believe, that nearly all the varieties of dilute oil of vitriol are true chemical compounds; and I think that we shall have sufficient evidence of this when we proceed to effect the various mixtures of sulphuric acid and water.

PHYSICAL PROPERTIES OF OIL OF VITRIOL.

The stronger varieties of sulphuric acid, have an oily, or rather syrupy, appearance; and those which contain more than 85 per cent. of real acid, have the property of fuming in the air. Oil of vitriol, when pure, is entirely without colour and smell. It is a heavy liquid, having a specific gravity which may be nearly double that of distilled water; the weight of the acid, however, varies with its strength; for while the Nordhausen acid frequently has a specific gravity of 1900 (water being 1000), the strongest acid of English commerce never exceeds the density of 1845. This, in fact, is, the number which has been chosen by the Colleges of London, Edinburgh, and Dublin, in order to designate the standard strength of the strong sulphuric acid of their Pharmacopœias; but it is very difficult to procure an acid of such a density; or, having procured it, it is very difficult to keep it at that strength, for the very strongest oil of vitriol which can be obtained by our mode of manufacture, never exceeds the density of 1845·5; and the affinity of this acid for water is so great, that small quantities of it cannot be exposed to the air even for a few minutes without its specific gravity being more or less lowered. To judge from my own experience, I am disposed to think, that good commercial samples of oil of vitriol generally range between 1836 and 1840; but, as from accident or design, the acid may become still more diluted, so its density will sink even below the smaller of these numbers. In order to exhibit to you, therefore, the relative strengths and weights of such acids, I have brought before you this Table, which has been taken from the monograph of Dr. Ure.

TABLE exhibiting the RELATIVE PER [illegible] of ANHYDROUS SULPHURIC ACID, in [illegible] of Different Densities.

Sp.	Per Cent. of Dry Acid.	Sp. gr.	Per Cent. of Dry Acid	Sp. gr.	Per Cent. of Dry Acid.	Sp. gr.	Per Cent. of Dry Acid.

1708·0	65·23	1436·0	44·85	1218·4	24·46	1033·6	4·08
1697·2	64·42	1426·5	44·03	1210·8	23·65	1026·6	3·26
1686·0	63·60	1417·0	43·22	1203·2	22·83	1020·6	2·446
1674·4	62·79	1407·8	42·40	1195·6	22·01	1014·0	1·63
1662·4	61·97	1397·7	41·58	1187·6	21·20	1007·4	0·8151

In presenting this table to you, I ought to remark that I have generally found that Dr. Ure has slightly underrated the true amount of dry acid in these solutions; and I must beg your attention to another table, which is founded on my own experiments, in order to illustrate this.

TABLE showing the QUANTITY of ANHYDROUS SULPHURIC ACID IN LIQUIDS OF DIFFERENT DENSITIES.

Specific Gravity.	Per centage of Acid.	Specific Gravity	Per centage of Acid.
1840·9		1136·2	16·41
1616·8	61·54	1014·8	1·65
1548·6	54·70	1008·2	0·82
1390·0	41·02	1004·8	0·41
1245·4	27·8[illegible]	1002·3	0·2[illegible]

Again, questions may arise in a court of law as to the bulk and weight of some popular measure full of one or other of these acids; and although such questions can never involve any matters of very great importance, yet it is right that you should be put in a position to answer them. To this end you are to bear in mind that a tea-spoonful of distilled water measures about ʒj., and weighs about 60 grs.; that a tablespoonful measures from ʒiv. to ʒvj., and weighs from 240 to 360 grs.; that a wineglassful of this liquid measures from ℥iss. to ℥ij., and weighs from 720 to 960 grs.; and that a teacupful measures about ℥v., and weighs about 2400 grs. Having these data before you, or, what would be still better, the absolute bulk of the vessel employed, you can readily make the desired calculations. Supposing, for example, that a question arose as to the bulk and weight of a teaspoonful of acid which had the specific gravity of 1836: you will answer that a teaspoonful measures about ʒj., and in order to arrive at the weight of the acid we employ a simple rule of three, and say, that as 1000 (the sp. gr. of distilled water) is to 1836 (the sp. gr. of the acid in question), so is 60 (the weight of ʒj. of water) to 110·16 (the weight of ʒj. of the acid).

The boiling point of oil of vitriol is another physical property which we ought to consider, and we shall find that while the Nordhausen acid boils at about the temperature of 120 of Fahr., that of English commerce requires a degree of heat as high as about 600°, in order to be converted into vapour. The weaker acids, however, may be distilled at much lower temperatures; for, according to Prof. Graham, an acid having the specific gravity of 1780 will boil at a temperature of 435 of Fahrenheit, and that which has a density of 1650 will boil at the temperature of 350° Fahrenheit, and so, as we weaken the acid, is the boiling point reduced. Again, we find that, when we take a weak acid, and subject it to distillation, the greater portion of its water is

first driven off, and the boiling point is continually rising, until, in fact, the acid acquires a density of 1845·5, when the temperature at which it vaporises is 620°. So again, with reference to the Nordhausen acid; while the strong acid at first boils at about the temperature of 120° Fahrenheit, yet, as the process of distillation is carried on, the acid becomes weaker, and the temperature is continually rising until it ultimately boils at 620° Fahrenheit. At this time it will be found that the liquor contained in the retort is no other than common oil of vitriol, having a specific gravity of 1845·5.

CHEMICAL PROPERTIES OF OIL OF VITRIOL.

1st. *With regard to its affinity for Water.*—Sulphuric acid has a great affinity for this liquid, insomuch that when the ordinary acid is exposed to the air it will rapidly absorb moisture therefrom and acquire an increase of weight; in fact, during very damp weather this increase may amount, in the course of twenty-four hours, to one-fourth of the weight of the acid employed. We find, also, that when oil of vitriol is poured upon organic substances it generally discolours them, in consequence of its attracting water, or the elements of water, and liberating carbon. Again, when sulphuric acid is mixed with water, it commonly gives rise to a great exaltation of temperature. Dr. Ure states that a mixture of four parts by weight, or of two by measure, of a concentrated acid, having the density of 1845, with one of water, will produce a temperature as high as 300° Fahr. This circumstance may be of some importance in a medico-legal point of view; and I have, therefore, been at great pains to ascertain the temperature and condensation which result from the mixture of water with acids of different strengths. The following table exhibits the general tenour of my experiments, and I ought to inform you that my investigations were made when the surrounding temperature was as high as 72° Fahr.

TABLE showing the HEAT and CONDENSATION which result from various MIXTURES of SULPHURIC ACID with WATER.

gr. of Acid used		Bulk of Acid used.	Weight of Water used	Bulk of Water used.		Bulk of Resulting Fluid when cold.	
1840	000	℥iij. & ʒvj.	1000	℥ij. & ʒij.	266		1616
1840	2000	℥iiss.	1000	℥ij. & ʒij.	252	℥iv.	1518
1840	000	℥i. & ʒij.	1000	℥ij. & ʒij.	210	℥iij.	1390
1840	500	ʒv.	1000	℥ij. & ʒij.	198	℥ij. & ʒivss.	1245
1840	250	ʒiiss.	1000	℥ij. & ʒij.	130	℥ij. & ʒiij.	1136
1616	616	℥ij. & ʒij.	1000	℥ij. & ʒij.	119	"	1282
1548	518	℥ij. & ʒij.	1000	℥ij. & ʒij.	108		1246
1390	390	℥ij. & ʒij.	1000	℥ij. & ʒij.	95		1170
1245	245	℥ij. & ʒij.	1000	℥ij. & ʒij.	81		074
1138	138	℥ij. & ʒij.	1000	℥ij. & ʒij.	78		055

From this Table, it will be evident, that both the heat and condensation are always greater in proportion to the strength and quantity of the acid employed. According to Dr. Ure, the greatest heat and condensation are effected when strong oil of vitriol and water are mixed in such proportions as to produce a liquid which has the specific gravity of 1,632·1; and I may remark, that the temperature is always a little higher when the water is poured into the acid, instead of the acid into the water. My experiments also inform me, that the temperature of the mixture rapidly falls; that, for example, when the heat produced has been very great, it falls in about ten minutes from thirty to fifty degrees below the original point; and, unless large quantities of the fluids have been used, the mixture acquires the temperature of the surrounding atmosphere in about half an hour.

2nd. *Action of Sulphuric Acid on Litmus Paper.*—For the most part, the action of this acid on litmus is very marked; but it begins to fail in producing its reddening effect, when its solutions are diluted so as to contain only ·015 per cent. of dry acid.

3rd. *Action of the Acid on Metals.*—When the strong acid is boiled upon zinc, copper, mercury, silver, &c., it undergoes decomposition, and evolves the vapour of sulphurous acid. This acid is recognised by its odour, (that of a burning match) and by its reddening and then bleaching a small piece of turnsol paper. A far more delicate test, however, for sulphurous acid, is the following:—Take about ʒj. of starch, rub it down with ℥j. of boiling water, and dissolve therein about 10 grs. of iodic acid, or iodate of potash; moisten a piece of white filtering paper with this solution, and hold it over the mouth of the vessel from which the sulphurous acid is being evolved; the paper will instantly acquire a deep blue tint. The action of this test is dependent on the power which sulphurous acid possesses of reducing iodic acid, and thus setting iodine *free*, which instantly produces with the starch a deep blue compound, iodide of starch. I shall have occasion more particularly to direct your attention to this test when I speak of the mode of detecting sulphuric acid in organic mixtures.

I have found from experiments, that acids which have a specific gravity below 1616, or which contain less than 61 per cent. of dry acid, will not act on metallic copper or silver, and will not, therefore, evolve sulphurous acid when they are heated with either of these metals. The dilute acid, however, will act, though in quite a different manner, on many of the common metals, as, for example, on zinc and iron. In these cases, the action is accompanied with the evolution of hydrogen gas; and you may perceive, from the slight effervescence which is here going on, that dilute sulphuric acid will act on these metals when its density is not greater than 1002. The action is even observable when the solution does not contain more than 0·00128 per cent. of dry acid.

4. *Action of Sulphuric Acid on Organic Substances.*—This part of our inquiry is of considerable importance to the medical jurist, and we shall, therefore, discuss it very fully. At the onset, however, I may premise, that the strong acid exerts a very energetic action on almost every kind of organic compound; and it does so either by abstracting water or its elements, therefrom; or by entering into union with the whole or a part of the organic group, or by being itself decomposed and converted into sulphurous acid, or hyposulphuric acid, the last of which generally enters into very intimate combination with the residual portion of the organic substance. Instances of each of these modes of action will occur to us as we proceed.

(a) *Action of Sulphuric Acid on Sugar.*—Strong oil vitriol acts directly on every species of cane sugar, and causes a marked discoloration of this substance. It does so in consequence of its liberating charcoal by abstracting water, or the elements of water from the organic group. This effect is very manifest when we pour oil of vitriol upon strong syrup. It is even evident when we use an acid, the density of which is no greater than 1616, provided we add it to the solid sugar; but when the sulphuric acid is diluted so as to bring its specific gravity down to about 1400, it requires time,—that is, a period of two or three hours, for the manifestation of this effect, and even then, with an acid of the last named strength, the discoloration is not very complete. Solutions which are weaker than this do not, at ordinary temperatures, exert any marked action on saccharine matter; but if the temperature be raised, and the liquid evaporated, it will be found that even ʒij. of a solution which does not contain more than 0·005 per cent. of *free* acid,—that is, about the 6-1000ths of a grain, will readily char about five grains of sugar. Now, as questions of an intricate and somewhat contradictory nature have been raised in Courts of Law with regard to the results which follow from the mixture of oil of vitriol, water, and sugar, it is important that we should examine this point in a very careful manner; for an Advocate's defence has, and for aught I know, may again be constructed on the supposition that a person might ignorantly administer sulphuric acid upon a lump of sugar, believing it to be spirits of anise, gin, or some other colourless cordial. Let us see, however, whether the facts of the case will bear out such a supposition.

If we put a few drops of oil of vitriol, having a specific gravity above 1600, upon a little sugar, it will instantly char it; and this effect is still more marked when we drop a piece of sugar into a teaspoonful of such an acid; so that it is hardly possible for any individual to perform such an act under the belief that he is using a cordial, without instantly discovering that a mistake has been committed.

It may happen, however, that the proceeding is conducted in a different manner, and that the sugar is first put into a little water, and the *spirit* afterwards added to it. Put, therefore, a knob of sugar into a procelain basin, and pour ʒj. of water upon it, then add ʒj. of oil of vitriol, and you will observe that the sugar is instantly blackened, and that the temperature of the mixture rises to about 180° Fahr. If we use ʒij. of water, the same kind of discolouration is effected, and the temperature rises to 176 Fahr. On using ʒiij. of water, the sugar is still darkened, and the temperature rises to about 170 Fahr. And, lastly, if we employ as much as ʒiv. of water with ʒj. of acid, there is still a transient discolouration over the surface of the sugar, and the temperature of the mixture rises to about 140° Fahr.; so that, to say nothing about the acidity of these mixtures, and the fact that nurses are accustomed to taste such liquids before they administer them to young children, it would be absolutely impossible for any individual to commit a mistake of this kind without instantly perceiving that something had gone wrong in the matter.

Mr. Taylor has discussed this question in his recent Work on Poisons, and he has come to a like conclusion, for he says, by way of comment on some experiments, which are therein mentioned:—"Thus, then, it will be seen, that even by putting acid and water, or water and acid, before the sugar, the carbonizing action of the acid is well marked. It is only when the acid and water are *thoroughly intermixed before* the addition of the sugar, that the liquid does not become blackened."

(b) *Action of Sulphuric Acid on Flour and Starch.*—When the strong acid of sp. gr. 1800 is poured on flour, it renders the latter substance of a deep violet red colour; but an acid having a density below 1800, does not, at ordinary temperatures, affect the colour of farinaceous substances. The production of this colour is due to the gluten which is contained in ordinary flour, for the acid will not act in this way upon pure starch, but will require time for the carbonization of this substance. When, however, a weak solution of sulphuric acid is boiled with any kind of feculent matter, it converts the starch into sugar, and the liquid loses the property of being coloured blue by iodine. I find that very small quantities of acid have the power of effecting this change; for if we take an ounce of a liquid which does not contain more than half a grain of free acid—that is, about 0·1 per cent. of it, and boil it in a flask on one grain of starch for about one hour and a half, or until it is nearly dry, and then add enough water to make up the original bulk of the liquid, it will be found that the whole of the starch has been decomposed, and that the solution has lost the property of acquiring a blue tint when it is tested with iodine.

(c) *Action of Sulphuric Acid on Wood.*—A strong acid of specific gravity above 1700 chars wood directly it touches it, while an acid, the density of which is between 1600 and 1700, require a few minutes for the manifestation of this action, and then the wood merely acquires an olive-green tint. Again: Those acids which range between 1600 and 1400, will not produce such a change unless they are allowed to stand on the wood for about twelve hours; and weaker solutions of the acid do not effect any discolouration whatever of the ligneous tissue.

(d) *Action of the Acid on Paper.*—Those specimens of oil of vitriol which have a density above 1800 act immediately on white paper; for they discolour it, and rapidly dissolve it; while those acids which are weaker than the last-named do not effect any immediate visible change on this sub-

stance. If, however, we sprinkle a little dilute acid, the density of which may be as low as 1100, on white paper, we shall find that there is some difficulty in getting the paper dry; and when this is effected, the paper will either turn black where the acid has fallen on it, or it will become very brittle and crumble away when it is rubbed between the finger and thumb. This property is manifested by solutions which do not contain more than 1-200th per cent. of free acid.

(e) *Action of Sulphuric Acid on Linen Cloth.*—Acids which possess a specific gravity above 1700 will carbonize linen cloth directly they are dropped on it. It will be found, moreover, that in the course of from five to fifteen minutes the fibre of the cloth is either completely corroded away, or else it is so rotten that it tears on using the slightest force to it. Acids which have a density between 1700 and 1600 will also darken such a fabric, but the corrosion of the tissue is never so manifest, notwithstanding that it becomes very rotten after a period of twelve hours. This property of rotting the cloth in the course of from twelve to twenty-four hours, and of keeping it damp, is possessed by solutions which do not contain more than the 1-200 per cent. of free acid. You will remark, moreover, that in those cases where the discoloration has been very complete, the original white tint of the linen is often restored when the cloth is steeped for a few minutes in water.

On reviewing the facts which I have here detailed, it will be manifest that sulphuric acid exerts a marked action on all the common forms of vegetable substances; and that it does so when the acid is strong, in consequence of its affinity for water, or for the elements of water; for in all those cases in which a marked discoloration has been effected, the organic molecule has suffered a more or less complete disintegration, its oxygen and hydrogen having been removed, and its carbon set free. When, however, the discoloration has not been so manifest, and we have employed a weaker acid, the elements of the organic molecule appear to have been reduced to a simpler group: in the case of cane sugar, for example, which consists of (C_{12} H_9 O_9 + 2 aq.), it is converted, without any discoloration, into grape sugar, which has a composition of (C_{12} H_{14} O_{14}) and so with regard to starch or flour, the great bulk of which is composed of (C_{12} H_9 O_9, HO + 2 aq.), of wood or linen cloth, the basis of which is cellulose, (C_{24} H_{21} O_{21}). Dilute sulphuric acid has the power of reducing these bodies to simple structures, and of converting them into grape sugar (C_{12} H_{14} O_{14}).

It is in this way that we are enabled to explain the difference in the action of strong and of weak acids, the former of which abstracts water, and so carbonises the vegetable substance, while the latter slowly converts it into grape sugar, which crumbles away or dissolves when the tissue is rubbed or put into water.

At our next meeting, gentlemen, we will proceed to inquire into the action of sulphuric acid on animal substances.

LECTURES ON OPERATIVE OPHTHALMIC SURGERY.

DELIVERED AT THE CENTRAL LONDON OPHTHALMIC HOSPITAL.

By H. HAYNES WALTON, Esq., F.R.C.S., Surgeon to the Hospital, and to the St. Pancras Royal General Dispensary.

LECTURE III.

Cataract.—Importance of a proper selection of Cases for Operation.—A healthy iris a valuable index of a healthy eye.—Inquiry into the size and motions of the pupil, and the effect produced in them by cataract.—State of retina, and general condition of globe.—Difference between cataract and amaurosis, and cataract and glaucoma.—Preparation of patient for operation.

GENTLEMEN,—It is not enough to recognise cataract, or to distinguish the different forms of it; you must be able to decide when a case may be operated on with fair prospect of success, and when the operation should not be attempted.

The most valuable criterion for our guidance in this respect, is the condition of the pupil, with the different changes it presents, according to the degree of light to which the retina may be subjected.

Whenever the deep-seated textures of the eye are diseased or impaired, the iris is influenced either from extension of morbid action, or functionally, so that it ceases to be a freely-acting muscle, and may be said to be unhealthy, and a sufficient index that the globe is unsound and an operation inadmissible. The converse of this does not always hold good. When I speak of the difference between incipient cataract and amaurosis, I will point out at least one notable exception.

The iris may have been diseased, without permanent injury to other parts of the eye, or even to itself, beyond mechanical hindrance to its motion from adhesion of the pupil. Adhesion alone would not prohibit operation; but if, with it, the iris has lost brilliancy and colour, the probability is, that the disease has, by its intensity or duration, spoiled or materially affected some or all of the important tissues of the globe.

Where there is an irregular pupil, with imperfect movements, adhesions must be suspected, and, if not at once detected, sought for by using belladonna, which will always dilate the free portions, and make apparent any fixed parts. Indeed, all cataractous eyes should be submitted to its influence; for, when least suspected, such adhesions, more or less partial, may be present, and a knowledge of the slightest confinement of the pupil is of consequence, as I shall show when describing the operation of extraction.

As the size of the pupil varies in different individuals under the same amount of light, it is not, taken alone, worth much as a diagnostic. Your own observation must have furnished you with instances of individuals in whom it varied considerably, and who, notwithstanding, saw equally well. There is a relation, I do not say invariable, but sufficiently constant to be recognised, between it and certain temperaments,—a fact too often overlooked. In the same person there should be no disparity of size, although cataract be more advanced in one eye than the other, or one be not even implicated.

It is the action of the pupil, then, and not the dimension, that is of such value, although, in that you will find variation in different persons within the range of health, and in the same persons at different ages. Generally speaking, the smaller the habitual size of a pupil, the slower and more limited will be its movements.

Cataract acts as a veil to the retina, renders it less sensible to light; and the capsulo-lenticular form may, from its great opacity, so effectually cut off external impressions, as to render the pupil motionless under the ordinary light of day, but such cases are uncommon. If, after shading an eye, and then exposing it to a bright light, the pupil does not act, suspicions may justly be entertained of the unsoundness of the retina. The eye not the subject of the experiment should be closed.

An applicable rule is, to expect contraction and dilatation according to the opacity of the cataract; while it is incipient, the pupil is uninfluenced, except the cataract press on the iris and impair and prevent its movements; the certainty of any action, therefore, however slight, may be satisfactory.

I have seen a few cases of remarkable activity of the pupil, considering the opacity of the cataract. In May last, at the request of one of our Committee, I was called to see a patient in private life, aged 81, with cataract in each eye, one of which was dark, the other nearly so. I took her to the window; the day was not bright, and the pupils were so small as to induce me immediately to suspect the existence of something more than cataract; but when the eyes were examined by being alternately covered and exposed to light, there was a variation in the size of the pupils that surprised me. She was herself aware of the effect of the light, for the disadvantage accruing from it had obliged her, ever since the commencement of the cataract, to wear a large shade. I operated on the left, the darker eye, and recovery of sight followed without a single bad symptom.

When there is internal disease of the eye, the pupil is nearly always dilated—frequently to a considerable extent—and is often irregular, and the nature of the case is palpable. The opposite condition to that, namely, contraction, especially in a great degree, is rare.

I said, that in proportion to the natural size of the pupil will be its action; and when that is very small, and cataract exists, it is possible, in many cases, that it may appear fixed: the motion, if any, not being appreciable, the power of discerning light is not, in itself, enough to warrant an operation.

The application of belladonna to the conjunctiva of a healthy eye, always produces *decided* dilatation of the pupil, be its natural size what it may. It is well known, that very slight changes in the iris, that can scarcely, if at all, be detected by external examination, will diminish or destroy its effect. I have shown, that an unhealthy iris is an index of an unhealthy globe; and the idea occurred to me, whether belladonna may not sometimes be used with advantage to test the integrity of the organ. I believe that it may. Here is a case in point:—

An old man was sent to me in February of this year. The right eye had been operated on by Mr. Tyrrell, and for several years afforded good sight, notwithstanding considerable prolapsus of the iris and displacement of the pupil to the margin of the cornea, and then became dark. In the left was a lenticular cataract. He could see the shadow of his hand. The iris appeared healthy. The pupil was very small, unadherent, and, for aught I could see, motionless. The globe seemed to possess its natural firmness. Belladonna, and afterwards atropia, produced but *a very inconsiderable effect*. My prognosis was unfavourable. He pleaded hard for a chance; I yielded, and operated. The cornea united, and the eye gradually shrunk. There was throughout little local inflammation, and almost an absence of pain. The termination shows that the eye was unhealthy. I have not investigated, as far as I desire, the effect of belladonna on the pupil of morbid eyes. Dr. Mackenzie, when speaking of the action of the iris, says, "that if belladonna be applied for the purpose of dilating the pupil, in half an hour the effect will be accomplished, if the case be one of cataract; but after several hours there is generally little dilatation produced if amaurosis be present." This statement is too much generalized, and too loose to be of any worth. In individual instances, in certain kinds of amaurosis, attended with certain changes in the eyes, it will hold good; but decidedly it is not generally applicable.

That the retina should possess its natural integrity, is important; and, although it is impossible, in particular cases, to say with certainty whether only slight perception of light be owing to intense opacity of the cataract or not, and especially if the capsule be opaque, generally speaking, the degree of vision is a pretty sure index of the health of that tunic. An operation undertaken when it is feeble, must always be regarded as a doubtful proceeding; with total darkness, it would be wholly inadmissible.

A small body, such as a penknife or the finger, should be passed between the patient's eye and the light; and, if he perceive it, the retina may be considered sound, and less healthy in proportion as larger bodies are required for discernment.

Certain conditions of the globe indicative of changes in the vitreous humour so far mar, or render operations abortive, or have such an untoward tendency, that they should always be detected when present. They are softness, or "hogginess," as it is called, or the opposite state, unnatural hardness, each being attended with a dissolved state of vitreous humor, the former showing also a diminution of it.

A tremulous or paralysed iris is so frequently seen in connexion with defective nervous power and unhealthy vitreous humour, that I should be very loth to operate when it exists.

The following case came under my notice a few years ago:—A lady, aged 50, became affected with cataract in both eyes; her general medical attendant prevailed on her to allow him to operate. The right eye was committed to his care; failure fol-

lowed. He used the needle. I suspect that he depressed. Six years after, returning sight in the left eye showed that the cataract was being absorbed. When I examined her in London, a period of twelve years from the date of her fortunate discovery, both irides were very tremulous, more so than I ever saw in any individual. The right pupil was adherent in several places to irregular portions of opaque capsule, some of which were partially loose. The pupil of the left eye was perfectly clear. With proper cataract glasses, she had good sight, and read for some hours daily in books of large type. I suspect that the irides were tremulous prior to the operation on the right eye, and the absorption of the lens in the left; and, if so, here is an exception to the statement I made of the combination of a weak or imperfect retina with a tremulous iris. As we proceed we shall see that paralysis of the iris is not uncommon after a cataract has been removed by absorption or otherwise. Dr. Farre also saw the lady. The spontaneous disappearance of the cataract in the left eye is another reason for mentioning the case.

Discoloration of the sclerotica, or unusual vascularity, especially if the vessels are large and vitreous, shrinking of the eyeball, or disproportionate size of the cornea, may all of them be viewed as unfavourable prognostics to operating, and any one of them may be sufficient to militate against it.

Without proceeding further into detail, it may be stated as a rule, that any deviation whatever in any of the textures composing the globe, except the lens, from what would be considered a state of health, is more or less obnoxious to surgical measures. Inflammatory affections of the lids, or mechanical changes in them, that may in any way produce irritation of the cornea, or interfere with their proper motions over the globe, come under the same category.

When cataract has been consequent on inflammation of the internal parts of the eye, the history of the case will point out its nature.

This short sketch of complications must be followed by recounting briefly the broad distinctions between cataract and amaurosis, and cataract and glaucoma. If I am to define amaurosis as imperfection or loss of vision depending on lesion of the ocular nervous apparatus, I am not aware of any objective symptoms besides the motions of the pupil and the directions of the eyeballs that can be depended on, and these furnish exceptions.

The paleness or light yellowness observed just behind the pupil, and considered as a symptom, is no such thing, but only the effect produced by the coloration of the lens, of which I spoke in the last lecture, and which would be seen with or without amaurosis. Young amaurotic persons never exhibit this appearance. In rare exceptions, the pupils act as in health when total blindness exists; (I shall not open the physiological question that this involves;) but the rule is, that their motions are greatly impaired, or quite lost, directly that vision is affected, and irregularity with dilatation is common.

Amaurotic eyes have a tendency to lose their parallelism, they usually diverge; are indefinite in motion and appear not to be under the control of volition.

In uncomplicated cataract, they are parallel, and their motions are regular, and in unison with the general movements of the body.

Now let us contrast the subjective symptoms of the two. Cataract forms slowly, and vision declines in proportion, and objects are enveloped in a mist. A dull or subdued light is preferred by the patient, because with the expanded or dilated pupil he sees better. In amaurosis, the sight may be gradually lost, but as frequently it departs quickly, or it may be suddenly; and muscæ, flashes, coruscations, pains of the orbits, headache, or other cerebral disturbance accompany the failing or lost vision, and a bright or strong light is generally sought for. The patient may see better one day, and worse another, and the extreme degrees may be very great. Luminous bodies appear distorted, or broken up into rays or stars. It can be only in the incipient stages of either of these affections, that a mistake is likely to be made, or a doubt raised.

Muscæ volitantes are frequently seen in connexion with cataract. They form, *per se*, no objection to an operation. Not unfrequently, after a cataract has been removed, the patient discovers, for the first time, that he is the subject of them. Whenever the formation of a cataract is accompanied with uneasiness or pain in the eye, or its surrounding parts, suspicions should be entertained of other disease, and it must be borne in mind that it is common for cataract to co-exist with amaurosis or glaucoma.

Glaucoma, not uncommon in elderly persons, but I believe never seen in early life, signifies a green state of the pupil, with other changes in the eye. At first it is light green, but becomes deeper as it advances. Hardness of the globe is a common attendant. The following paragraph from Dr. Mackenzie's work expresses all that I need tell you. "Limited and sluggish motion of the pupil, "with other amaurotic symptoms, always attends glaucoma. Ultimately the pupil is dilated, and the retina insensible to light. The loss of sight, however, is generally very gradual, and is sometimes attended, at least for a time, by diminution in the size of the pupil."

There is considerable difference of opinion about the nature of glaucoma. Some speak of it synonymously with acute retinitis, others as chronic arthritic inflammation of the internal tunics. Dr. Mackenzie considers that he has proved the lens to be the original and only seat of the green appearance his arguments are ingenious, and scientific, and plausible, but decidedly not conclusive. Of this you may be certain, that opacity of the lens, combined with any tinge of green, is always attended with such other changes in the eye as to prohibit operation.

The catoptrical, or candle-test, as it is called, of Sanson, I am not in the habit of employing. I have not found it of any assistance in the very commencement of cataract, when there has been a question of opacity; and in a more advanced stage I do not require it. It is said to be satisfactory in pointing out the difference between cataract and glaucoma. Dr. Mackenzie discusses the subject at large in his treatise, to which I refer you.

Operations, implicating the globe of the eye, demand for their success a particular state of health —that in which an injury can be inflicted on a delicate and sensitive organ with the greatest impunity. It is a mistake to depress the patient to a very low degree; I believe that would be as bad as the opposite or plethoric state, which should be always avoided. A certain amount of healthy action is required to resist and to repair. In the operation of extraction, when the cornea is cut, unless union be quickly effected, by first intention, or, more correctly, by adhesion, the result, always more or less imperfect, may be destruction of the organ.

An accustomed eye soon detects a plethoric person, or one that is popularly said to be in "rude health." Such an one should, by regulation of diet, exercise, and, if necessary, purgation, be reduced till those symptoms disappear, and the circulation is reduced rather below par. On the other hand, a debilitated constitution requires to be improved and brought to the proper standard. It is impossible to define by word what that exactly is, but every practical man will know what is meant. It is important that the digestive organs be in health and the tongue clean.

The presence of specific inflammation, as the strumous, gouty, syphilitic, or rheumatic, in other parts of the body would contra-indicate operation; nor would it be prudent to operate on an eye that had been recently inflamed. A very long interval should be allowed to pass after the last trace of such disturbance.

Organic disease of the chest, provided cough be not produced, or perhaps of some of the abdominal viscera, may offer no impediments. While a pupil attending the practice of Mr. Terryll, he operated by extraction on one eye of a female aged 57, who had valvular disease of the heart, ascites and anasarca. The operation was quite successful, and she returned home on the eleventh day after its performance. Her heart had been diseased for five years.

Advanced age is not an objection to operation, if nothing else forbid. The most complete result has followed extraction after ninety. The late Mr. Scott operated with success on a female between ninety and a hundred. I have frequently operated after the eightieth year. During this summer four times—three of the patients were in the Hospital, the one in private was in his eighty-sixth year.

The late Dr. Lynch requested me to see a workhouse patient with cataract, who had been bed-ridden for several years, from loss of motion in his legs. He must have been of a very great age, judging from the physical changes his frame had undergone. At the old fellow's request I operated on one eye: he was enabled to read.

It is a point fully settled, that no treatment is available for cataract but the operative,—that hard cataract ought either to be extracted, by which it is at once removed from the eye, or displaced; that is, pushed away from the pupil to the lower part of the vitreous humour; while the soft cataract, being allowed to remain in its position, is lacerated or divided, that it may be absorbed.

The following important questions are often put to the ophthalmic surgeon:

Should one eye be operated on while the other is yet sound?—The only reasons I know of for the affirmative, are, that a personal deformity is removed, and that any amount of sight that can be made available for viewing bodies situated laterally, and out of the reach of both eyes at the same time, is advantageous. While opposed to this is the probability of confusion of vision ensuing when the same bodies are viewed with two eyes of a different focal range. I cannot tell why, in some instances, this confusion exists, while in others it is absent. So very uncertain is the period at which the second eye becomes affected, that no one can venture to offer an opinion. My own experience furnishes examples of very distant intervals. The last I recorded was sixteen years, and in some cases it may never be involved. Therefore we have no right to operate in anticipation of such an event. But as soon as the other shows implication of cataract, or of failing sight from any other cause, there is no reason for delay if the patient wishes for an operation on that most affected.

Should both eyes be operated on at once?—If extraction, decidedly not. Let one recover before the other is touched. When I first commenced practice, I frequently operated on both at the same time; but I am now convinced that it is imprudent. For depression, or solution, it matters not, and may be left to the choice of the patient or the surgeon.

What time of the year is best suited for operating?—I have operated at all periods, with, as far as I could judge, equal success; but I am very careful if I extract in cold weather, to have the sleeping-room of the patient, the one to which he is confined for the first few days, kept at a uniform temperature, and not lower than 60 degrees of Fahrenheit. The prevalence of easterly winds, or of damp or rainy weather at any time, would be objectionable.

In December of last year, when the weather was mild, I arranged to extract a cataract from a female, aged 71; the 21st, the time appointed. When the day arrived the frost had set in, but I would not postpone the operation. With the aid of a good nurse all my regulations were carried out, and on the 26th, two days after the frost broke up, the eye was opened, and the patient could see. This case would be of little value, were it not one of many others. Yet I consider that the summer months are preferable for extraction, because less care and attention are required, and the patient is better able to expose himself, and to take air and exercise, and recover his lost strength and spirits, the consequence of anxiety, and confinement, and preparation. Mr. Tyrrell thought it better, if possible, not to extract, except between March and October.

Notwithstanding all the difficulties and dangers that attend extraction, it possesses its advantages over the much easier operation of displacement, and practised by the best and most successful oculists.

I almost invariably extract hard cataracts, no because I have tested the merits of the two modes of operating, but guided by the weight of authorit and the example of my teachers, and, reasoning or their principles, from the earliest period of m practice I have adopted it.

This is the most fitting time to introduce the subject of chloroform. Any remarks on its use, except in the operation for extraction, and I ma add artificial pupil, when the cornea requires to be opened to any great extent, are not needed. Under those states employment is decidedly very dangerous, except certain precautions be used, becaus vomiting would in all probability cause destructio of the eye by the loss of the vitreous humour.

I have used it on five occasions, in each instanc by the particular request of the patient. The necessary precautions are, that the stomach be empty, and that the chloroform be given very slowly, and no more used than is just enough to produce insensibility. Four of the operations were hospital ones. All of them did well, slight nausea ensued, but neither retching nor vomiting. Consciousness returned quickly.

The fifth instance was a private patient, introduced to me by Mr. Harding, of Percy-street, who assisted me. The right eye had been lost under other hands a year or two before. You may suppose I was emphatic enough about not eating for some hours before the choloroform was to be inhaled. While arranging matters prior to operating, I asked her daughter, who was in attendance, if any food had been taken since the morning, it being then after one o'clock; the answer was, No.

The cataract was extracted, but no sooner had I finished, than copious vomiting commenced, and at each effort a gush of vitreous humour streamed down the cheek. Of course the eye was lost. The truth, now told, came at the wrong end. Half an hour before I was expected, the foolish woman "had taken a little luncheon with some porter, to give her strength."

It must be obvious that an empty stomach, and a very small quantity of chloroform, are security against vomiting at the time; but at any period within the first twenty-four or thirty hours, vomiting with retching may come on when the slightest portion of any liquid or solid enters the stomach; and the retching that may arise without partaking of anything might be quite as bad in results as the most copious vomiting.

In five cases of artificial pupil, in which chloroform was employed, I have not had to regret its use, although sickness ensued in two, and vomiting in one. I may say, that I have ceased to employ it.

Generally speaking, those who are the subjects of extraction are usually of an age to forbid the exhibition of any stupifying agent.

In surgical operations of a general character, no one has a higher opinion of chloroform than myself, provided it be employed judiciously, and administered by an experienced person.

ON THE

INVESTING FIBROUS MEMBRANE; OR FASCIA OF THE HEART.

By ROBERT LEE, M.D., F.R.S.,
Fellow of the Royal College of Physicians, London; Physician to the British Lying-in Hospital; and Lecturer on Midwifery at St. George's Hospital.

It was an opinion entertained by Haller and some other distinguished anatomists, towards the close of the last century, that the muscular substance of the heart has no nerves, and that its contractions do not depend upon nervous influence. In 1792, J. B. J. Behrends, a pupil of Professor Sœmmering, published a Memoir, which was entitled "Dissertatio qua demonstratur Cor nervis Carere," in which it is affirmed, in the most positive and unqualified terms, that not a single nervous filament is distributed to the muscular structure of the heart. "Ac primo quidem nervorum cordis examini scrupulosius intendens," he says, "tum observando tum analogice concludendo, didici nullos omnino nervos ne surculum quidem in ipsum cordis carnem dispergi." An engraving, in which the trunk and a few of the principal branches of the left coronary artery are represented, as supplied with nerves from the par vagum and great sympathetic is appended to the memoir. In 1794 this striking error was exposed by Scarpa, who represented in his splendid engravings branches of nerves passing from the par vagum and great sympathetic to the heart, and accompanying the coronary arteries to its apex. In these figures only a few small filaments of nerves are represented on the human heart, which proceed to the muscular structure, and which do not accompany the coronary arteries, but in one of the engravings of the heart of the ox, large branches are represented, passing obliquely across the blood-vessels on the muscular fibres of the heart. On one of these branches accompanying the left coronary artery, there is a distinct ganglion, or ganglionic enlargement. In the plates of Mr. Swan, published in 1834, only a few small branches of nerves are represented, which accompany the trunks of the coronary arteries. Monsieur Chaissaignac, the translator into French of Mr. Swan's Work on "The Nerves of the Human Body," asserted in 1838 that the existence of nerves in the heart, independent of the blood-vessels, had never been demonstrated:—"L' examen anatomique n'a constate jus'qua present dans le cœur; que des nerfs arteriels; l'existence de filets nerveux independantes des vaisseaux est encore a demontrer." P. 23.

In 1845 several anatomists in this country asserted that the uterus had no ganglia, and only a few small filaments of nerves, like sewing threads, which they affirmed do not enlarge in the slightest degree during pregnancy; and in support of this opinion, the heart was adduced as furnishing a striking example of a powerful muscular organ acting without interruption from the beginning to the end of life, though very sparingly, or not at all, supplied with nerves. None of these anatomists themselves had ever dissected the nerves of the heart; and the plates of Scarpa and of Swan furnished the only evidence they could adduce in support of their opinion that the muscular substance of the heart, like that of the uterus, is almost entirely destitute of nerves.

In September, 1846, being dissatisfied with this evidence, I resolved to appeal to nature, and proceeded to dissect the nerves of the heart immersed alcohol, as I had done those of the uterus, with magnifying powers of six and twelve diameters. The investigation was carried on during two years, and from the examination which I have made of the nerves of the healthy and malformed fœtal heart; of the hearts of birds; of the heart of the child at the ages of six and nine years; of the heart of the adult in the sound state; of the human heart slightly and greatly hypertrophied, and of the heart of the young and adult ox, the following conclusions may be deduced:—1st. That the blood-vessels and the muscular structure of the auricles and ventricles of the heart are endowed with numerous ganglia and plexuses of nerves, which have not hitherto been described or represented in the works of anatomists. 2ndly. That the nervous structures of the heart, which are distributed over its surface to the apex, and throughout its walls to the lining membrane and columnæ carneæ, enlarge with the natural growth of the heart before birth, during childhood and youth, until the heart has attained its full size in the adult. 3rdly. That the ganglia and nerves of the heart enlarge like those of the gravid uterus when the walls of the ventricles are affected with hypertrophy. 4thly. That the ganglia and nerves which supply the left auricle and ventricle in the natural state, are more than double the size of the ganglia and nerves distributed to the right side of the heart.

This anatomical demonstration of the ganglia and nerves of the muscular substance of the heart completely overthrows the last remaining argument employed by those physiologists who still defend the doctrine of Haller, that the irritability and contractibility of muscular fibre is independent of nervous influence. This demonstration further clearly indicates the source of the actions of the heart as an entire organ, and how its detached parts can continue to contract after its total separation from the body. It likewise furnishes a satisfactory explanation of many phenomena observed in the progress and treatment of organic diseases of the heart.

In prosecuting this investigation into the nervous system of the heart, I found that the great difficulty of dissecting and displaying the cardiac ganglia and nerves, did not arise so much from their extreme softness, from their close and intimate connexion with the blood-vessels, or from the quantity of adipose matter in which they were imbedded, as from the presence of a dense fibrous membrane or fascia, which was interposed between the serous membrane and the muscular coat, of whose existence as a distinct tissue of the heart I had no suspicion when these researches were commenced. In the most recent systematic writers on anatomy, the heart was represented as consisting of muscular and tendinous structures, blood-vessels, nerves, and absorbents, enclosed between two serous membranes.

The serous layer of the pericardium which is reflected over the surface of the auricles and ventricles of the heart, is an extremely thin, smooth, and transparent membrane, which is torn by the application of the slightest violence after it has been separated from the fibrous membrane or fascia, which is situated between it and the muscular substance of the heart. If an incision be made through both these membranes over the left ventricle, it is not difficult, with a pair of fine forceps and a needle, to destroy the cellular tissue by which they are united, and to demonstrate the existence of a serous layer and fibrous membrane over the whole surface of both auricles and ventricles. On examining the fibrous membrane when thus exposed, it is found to be possessed of great strength and firmness, glistening, semi-transparent, and resembling, in all respects, the aponeurotic expansions, or fasciæ covering muscular organs in other parts of the body. It is much stronger over the ventricles than the auricles, and it adheres so firmly where it is in immediate contact with the muscular substance of the auricles and ventricles, that its separation often cannot be effected without tearing up some of the muscular fibres to which it is attached. From the inner surface of this fascia, which I have named the cardiac fascia, innumerable strong fibres pass to the blood-vessels, nerves, and muscular fasciculi and adipose matter. These strong, slender fibres, connected with or proceeding from the inner surface of the fascia, accompany and surround all the blood-vessels and nerves, and they are interlaced together so as to form a peculiar stroma, if it may be so termed, of considerable thickness, between the fascia and all the various structures beneath, which it invests and binds together in the strongest possible manner. These fibres form a complete sheath around all the arteries, veins, and nerves on the surface of the heart, and accompany them as they dip down between the muscular fasciculi to which their branches are distributed throughout the whole walls of the heart from the surface to the lining membrane.

From the preparations in the Museum of St. George's Hospital and in my possession, it is seen that the cardiac fascia exists in the hearts of the larger quadrupeds, in the human heart, in the healthy and hypertrophied states, and in the heart of the child at the ages of six and nine years. It can likewise be demonstrated in the hearts of birds, and it is this fascia which chiefly gives to the fœtal heart its re-

markable firmness when all the other muscular parts of the body are, as Mr. Hunter observed, in a soft and almost gelatinous state. "The muscle which has the greatest resistance in an animal body to overcome," he observes, "is the heart especially in quadrupeds, and this is, perhaps, the firmest in the body, being even firmer than those which have the above-mentioned resistance to overcome." "From the above account, it must appear," adds Mr. Hunter, "that muscles, in proportion as they are firm in texture, will be strong in action; it is at least demonstrable in the muscles of the same animal, whose texture is different, and similar muscles in the male and female of the same species; and we may reasonably suppose that it will hold good in different species; and, therefore, when we find the muscles very firm in any one species, we may conclude that this species is stronger than any other species in which the muscles are tender and soft." "The heart of all partakes strongly of the two causes of firmness, and is, perhaps, the firmest muscle in the body."

The cardiac fascia is obviously one of the principal causes of the firmness and strength of the central organ of the circulation of the blood, as it binds together into one mass, and gives support to the muscular fibres like the fasciæ investing other muscles. The cardiac fascia is to the heart, I believe, what the external fibrous coat is to an artery; and it must have nearly the same effect in preventing dilatation and rupture of the ventricles during violent exertion. The thin feeble serous covering of the heart can possess little influence, and add nothing to the strength of the parietes, and probably, but for the fascia now described, the heart would often yield, in all directions, especially at the apex. In a physiological of view, it, therefore, has appeared to me, that this fascia of the heart is one of its most important structures.

In a pathological point of view, the cardiac fascia is, perhaps, not less worthy of notice. Muscular structure, it is well known, is not liable to attacks either of common or specific inflammation. It is impossible to avoid suspecting, that rheumatic inflammation of the heart has for its principal seat, this dense fibrous membrane lying between the serous and muscular coats of the heart, and that attacks of rheumatism of the heart do not commence primarily in the muscular structure. The tunica sclerotica of the eye sometimes becomes inflamed, softens and yields, and from these changes, it is known, that sclerotic staphyloma and other diseases, are the results. Whether, in dilatation of the heart, a similar morbid change is not first set up in the fascia; and what influence this fibrous membrane has in modifying all the diseases of the heart, future observations must determine.

The appearances of the cardiac fascia in the human heart and in the heart of the ox have been beautifully and most faithfully represented in the engravings which illustrate my paper "On the Ganglia and Nerves of the Heart," very recently published in the "Philosophical Transactions," (Part i. 1849,) a copy of which paper accompanies this communication.

NEW VIEWS ON THE TREATMENT OF UTERINE DISEASES, AND OF THEIR ASSOCIATED NERVOUS AFFECTIONS.

By G. CALVERT HOLLAND, M.D.

Chapter I.
THE NATURE AND OBJECT OF THE PROPOSED INQUIRY.

I. Many years since my attention was directed to one branch of this subject by a distinguished friend and a zealous cultivator of pathology; (a) and, though I did not exactly coincide in the conclusions which he deduced from his researches, they had, nevertheless, this beneficial effect,—they imparted to a difficult and an embarrassing class of diseases a far higher interest than I had hitherto felt in the investigation and treatment of them.

(a) The late Dr. Mackintosh, Edinburgh.

Continued observations and gradually accumulated experience, as well as a more intimate acquaintance with the labours of others, in this particular department, convinced me, that, though the field had been occupied by master-minds, and many important advances had been made, much, however, remained to be accomplished. This is not expressed in spirit of presumption. Every one who gives to the world the results of his scientific or practical inquiries, flatters himself that on some points he is wiser than his predecessors. This is almost necessarily implied by the act of publication. I the superiority is not based on new discoveries, it may be traced to an imagined juster appreciation of the value of existing truths, and a finer sense of their application to the explanation of numerous phenomena. The presumption does not consist in the assertion, but in failing to establish the grounds on which it rests. Whether the uterus be studied in its impregnated or unimpregnated condition, it is clearly an organ peculiarly fraught with vital properties, and hence is susceptible of a variety of diseases the influence of which is not confined to its structure, but radiates in all directions modifying the functions of the entire animal system. At puberty commences the wide range of its sympathies, and the life to which it is awakened impresses upon every living fibre susceptibilities and powers not previously possessed.

From the moment the uterus enters upon a new sphere of duties, whether these be fully or only partially called into play, to their natural cessation from the progress of years, the normal, but especially the morbid effects which mark the periodicity of vital action or the interruptions to its manifestation, present unquestionably the most comprehensive class of phenomena emanating from, or associated with, a single organ, that the animal economy offers to our consideration. The difficulties connected with their investigation are referrible to the following circumstances:—

1. The uterus and its appendages lie out of the sphere of ordinary observation; and when examined with all the aids furnished by science, the knowledge acquired of their deviations from health is often only a remote approximation to the truth.

2. The structural changes detected in the uterus may be the cause of the constitutional symptoms, or, indeed, the effects of causes which are not seized or appreciated in all their importance, and, consequently, the remedies employed not being the suggestion of just and enlarged views concerning the nature of the existing derangements, will necessarily be inefficient or limited in the amount of good they confer.

3. The wide sympathetic relations between the uterus and the rest of the animal economy, from the anomalous and perplexing phenomena to which they give rise, tend, in a peculiar degree, to embarrass the inquirer in his efforts to define or trace the various disorders which originate in their disturbance. Our ignorance of the links composing the extensive chain of causation, as exemplified in uterine influence, is one great source of the imperfection of our knowledge on this deeply-interesting branch of research.

4. In the enumeration of the difficulties connected with the investigation and treatment of uterine affections, there is one which will readily suggest itself to the mind,—viz., the natural delicacy of the female. The unwillingness to make known the irregularities and disorders of the generative system, in their incipient stages when they would often be easy of correction, accounts for their aggravation and complexity, when they fall under notice, and proportionately obscures the view of the Practitioner.

II. We shall endeavour to show in the subsequent analysis of the rise, progress and nature of uterine diseases, that in none of the excellent works which treat of them, do we discover any clear or comprehensive principles elucidating, with anything like precision, the physiological conditions out of which they spring, on a knowledge of which alone all sound remedial measures must be based. This defect is not attributable to the want of talent in the writers, nor of abundant opportunities for accurate observation; but is to be referred to a limited acquaintance with the laws regulating the action of the vital powers generally. The attention hitherto has been too exclusively confined to the uterus, and the remedies employed have likewise been too exclusively applied to its structure. The pathologist has excluded from his consideration the light which physiology richly reflects upon his inquiries. In his study of the organic and functional changes of the organ, he has failed to perceive in their comprehensive and practical importance, the nervous and sanguineous relations which it maintains with the entire animal system—relations which not only supply the powers essential to the exercise of its functions, but through which it may be influenced to an extraordinary degree in the diversity of its disorders. The efficiency of these channels, carrying life and energy to all parts of the body, and of the mode in which they may be made subservient to the cure or alleviation of uterine affections, independently of all direct applications, either instrumental or medicinal to the organ itself, are comparatively little understood. It is ground which is largely unbroken.

The pathologist is familiar with the sources whence the uterus derives its nervous energy and blood; but has, indeed, much to acquire in regard to the application of a knowledge of these sources and of their relations to the animal system.

III. In the prosecution of this inquiry it is our intention to be thoroughly practical, by which is implied the suggestion of measures having an immediate reference to the treatment of disease. But let us endeavour to give a philosophical definition of the term. In its ordinary acceptation it too frequently means the employment of remedies on the authority of others, or on personal experience, but without being based on a just or enlarged view of their properties, or of the mode in which they affect the vital powers. The almost universal demand of the Medical Profession is for something practical,—some specific or agent of marvellous efficacy in the correction of morbid phenomena, unaccompanied with the imperative necessity of elaborately investigating the conditions of the animal economy, or of particular organs, on the due appreciation of which the whole of their beneficial influence will depend. Hence the unsettled, the ever-varying, and the widely clashing doctrines which characterise the healing art,—the vacillating routine of daily practice. With what avidity a new remedy is adopted on its announcement, or the novel application of an agent already known! This indicates an unsound state of the Profession. It displays a confidence in means irrespective of a commensurate anxiety to ascertain the laws and action of the vital powers,—a knowledge of which would materially lessen the prevailing credulous tendency of the mind. The meaning which we attach to the term practical, comprehends a knowledge of the vital conditions and of their modifications under particular circumstances; and, consequently, the remedies which will subsequently be brought under notice, will be the suggestion of physiological considerations, with the additional advantage of having been fully tested by extensive experience. The exposition

of the laws of vital action as exhibited by the uterine functions, is the first essential step towards a just conception of the origin and nature of their deviations from health; and it is the only method that can possibly lead to the establishment of efficient and philosophical views of practice. Every other course of procedure is empiricism, which, though not destitute of beneficial results, is nevertheless uncertain in its operations and exceedingly limited in the curative influence it exerts, compared with the employment of remedies founded on a knowledge of the physiological conditions and relations of the organs temporarily diseased.

IV. There is one striking advantage connected with the plan we propose to pursue that distinguishes none other: it will not only show the grounds on which the treatment should be founded, in reference to one particular class of morbid phenomena; but it will present such an insight into the functions of the animal economy generally, that the light elicited will have an application more or less direct to a far wider sphere of disordered vital actions. This is characteristic of truth. All principles possessing this property, whether they belong to inert or organic matter, to mind or life, are inexhaustible in the resources which they place within the power of man to control or modify the operations of nature. The labour of philosophy is less to discover new principles than to extend and illustrate those already known.

V. If we take an enlarged survey of the opinions entertained concerning the nature of uterine diseases and their treatment, we find the greatest possible discrepancy. By one writer, and one of the latest authorities on the subject, the symptoms are almost altogether to be traced to inflammation and its consequences, and the measures employed are almost exclusively local applications. By another, many of these symptoms are referred to functional derangement of the generative system dependent upon, or closely associated with the general state of the constitution, and the treatment enforced is in harmony with these views. A third perceives, as a cause of sterility, an obstruction of the os uteri and of the Fallopian tubes, and the necessity of its removal by mechanical means.

Whatever doctrine an individual lays down, and maintains with determined tenacity, naturally begets a tendency in the mind to see and study phenomena through the medium only which it presents, and it has a marvellous influence in moulding them agreeably to preconceived ideas. The success which is consequent on the treatment suggested, is the key-stone to the superstructure, and nothing further is imagined to be required to establish the soundness of the foundation. Unfortunately, recorded success seldom comes before us in such a form as to inspire implicit confidence. It rarely possesses the conditions essential to a correct judgment of its claims to attention. The state of the constitution, the properties of the remedies, and the mode in which they affect the powers of life, are never described with a sufficient degree of precision and accuracy to enable others to appreciate justly the value of the measures employed.

88, Mount street, Grosvenor-square.

ANTEVERSION OF THE UTERUS AS A CAUSE OF STERILITY.

By EDWARD RIGBY, M.D., &c.; Examiner in Midwifery in the University of London; and Lecturer on Midwifery at St. Bartholomew's Hospital, &c.

(Continued from page 583, Vol. XIX.)

Before quitting the subject of anteversion, I am anxious to direct the attention of your readers to an effect of this displacement, which has excited little, if any notice. But, in these days, when the speculum and caustic promise to be the diagnosis and panacea of all female diseases, deserve to be particularly mentioned. Cases of chronic inflammation of the cervix, with a swollen globular state of the anterior lip of the os uteri, are not unfrequently met with. The parts are hard, tense, swollen, and painful, and, on examination with the speculum, the anterior lip is much congested; its surface occasionally granular, or even abraded and ulcerated; the system is suffering generally from uterine irritation; there is the ordinary collection of local symptoms indicating inflammation of the os and cervix uteri, and the menstrual periods are attended with considerable suffering and derangement. By careful attention to the general health, and by local treatment, temporary relief is obtained, but nothing approach to a permanent cure—leeches, scarifying, lunar caustic, and even potassa fusa may be used, from time to time, and the changes diligently rung upon every species of injection; and thus, month after month passes; the local affection is, where it was when we first took it in hand, and the general health of the patient evidently losing ground. By a careful examination both with the sound as well as with the finger, we detect the fundus lying forward or, in other words, the presence of anteversion; we rectify this displacement, and, as in retroversion the swelling of the os instantly subsides. We keep the patient as much as possible in the supine posture, rectify the position of the uterus occasionally by the sound, or apply a supporter to retain it in its right position; the local symptoms cease, and the general health and strength improve by the removal of the uterine irritation, which had existed in consequence of the displacement. My attention was called to this fact by two or three cases among the out-patients at the Red-lion-square Hospital, where this state of the cervix, and especially of the anterior lip existed, and where, in spite of careful attention to general health and weekly examination of the part with the speculum no progress was made. The patient was still in suffering, the tongue showed the presence of irritation, the chylo-poietic functions always deranged, and the local affection defying all treatment beyond a very temporary degree of relief. I confess, that I had hitherto contented myself with merely inspecting the part when the house-surgeon had applied the speculum, thinking that this swollen and inflamed state of the anterior lip of the os uteri was the "*fons et origo mali.*" Becoming, however, dissatisfied with my want of success in relieving these cases, I determined to make a thorough and careful examination. The os uteri was invariably turned much backward; the uterus was inclined distinctly forwards, so that the body could be felt inclining towards the bladder; the uterine sound took the same direction. The patient had, among other symptoms, complained of pain behind the symphisis pubis, difficulty in retaining any quantity of water in the bladder, and frequently pain after passing it. On raising the uterus into its natural position, the globular swelling of the anterior lip instantly disappeared; it had become soft, thin, and lip-like; it was no longer tense, or painful upon pressure; in some cases, the uterus was carried upon the sound into a slightly retroverted position, and held there for a few minutes, with considerable relief to many of the old symptoms. In another case, Dr. Simpson's uterine supporter was required, and acted so far with success, that, although the anteversion was not cured, it did not return to the same extent as before, and she continued free from the symptoms of local congestion which had been so troublesome.

RETROVERSION.

Perhaps one of the greatest triumphs in diagnosis which have been achieved by the use of Professor Simpson's uterine sound, is the investigation of that species of uterine displacement called Retroversion, where the fundus is turned backwards, projecting into the recto-vaginal pouch; the os uteri being (though not always) turned forwards. In the *Medical Times*, of November 8th and 29th, 1845, and January 10, of 1846, I have described the characteristics of this displacement; I now return to it for the purpose of considering how far it can be a cause of sterility, and what are the effects which it is capable of producing. From the cases which have come under my observation, I should say there are few causes of sterility in an otherwise healthy woman of such frequent occurrence as retroversion, nor does it only occur where conception has never yet taken place, but even in patients who have had children.

In those patients where pregnancy has never taken place, and where, in all probability, it has existed for many years, it is chiefly the result of habitual constipation, the uterus not being able to bear the continued pressure of a heavily-loaded intestinal canal, aggravated, not only by occasional efforts of the abdominal muscles, but also not unfrequently by tight-lacing. In addition to these, which are merely mechanical causes, there can be no doubt, that whatever tends to debilitate the patient, to break down her tone and strength, and render the soft parts relaxed and flabby, strongly disposes her to this displacement; the uterus itself is soft and flabby, the vagina relaxed, and, therefore, a large amount of that support which maintains the uterus in its natural position, either entirely absent, or at least very imperfect. Thus we see it in feeble, dyspeptic young women, drained and blanched by leucorrhœa; but most of all do we see this cause of retroversion existing in women who have had an abortion; the uterus is now not only larger and heavier, but also much softer and more relaxed than usual, and, therefore, but little fitted to resist any mechanical force which may be applied to its fundus. This atonic state of the uterus and soft parts will modify the displacement considerably; if the uterus be chiefly affected, we shall probably have it bent upon itself (*retroflection*); the os uteri looking downwards, and but little, if at all, displaced; the fundus to be felt through the posterior wall of the vagina like a mass of scybala in the rectum. On the other hand, if the vagina and surrounding soft parts be chiefly relaxed, the displacement is strictly one of *retroversion;* the os uteri looks forward, and is much nearer to the symphisis pubis than natural; the uterus is not doubled upon itself as in the other case, but lies across the pelvis; the fundus pressing against the rectum, so that nearly the whole posterior surface of the uterus, from the os to the fundus, may be traced by the finger as it moves from before backwards.

The consideration of these different circumstances is useful, not only as enabling us to form a more correct prognosis, but also to modify our treatment according to the particular features of the individual case. Thus in cases depending entirely on loaded bowels, and where the displacement has probably not been of long duration, mild purgatives, which clear out the bowels effectually, increase their tone, and thereby diminish their calibre, and the occasional reposition of the uterus by means of the sound will occasionally be sufficient. I own, however, that these simple and fortunate cases are rather the exception than the rule. Where the displacement is of long standing, the assistance of Professor Simpson's uterine supporter will be required to preserve the uterus artificially in its natural position until by laxatives and appropriate tonics it is capable of maintaining that position without support. If it be a case of retroversion depending in a great measure on the relaxed atonic state of the vagina, &c.; the use of local astringents, in addition to the general treatment just mentioned, will usually be of much service.

In some cases, however, the supporter cannot be borne, its presence produces so much suffering, irritation, leucorrhœa, or even menorrhagia, as to forbid its use; or where the ovary has become so swollen and inflamed, in consequence of the displacement, as to render it impossible to return the uterus by the sound to its natural position, still less to introduce the supporter; in these cases the prone position becomes very valuable, and seldom fails, when maintained long enough, to remove the displacement, and reduce the swollen condition of the uterus and ovary which occasionally attends it.

Having taken this cursory view of the different conditions which require us to modify our treatment, I will endeavour to illustrate them by a few cases.

Mrs. A., aged 35; married a year and a half; never pregnant; brunette; tall.

July 6, 1848.—Complains of severe pain across the nates, and also of the left groin; the latter is much increased for ten days before the catamenial period. The catamenia last eight days; the discharge is scanty and brown; leucorrhœa in the intervals; lassitude; aching limbs; motions dark and offensive; tongue furrowed along the centre, and

covered with a thick bilious fur, through which project numerous red papillæ. She has suffered much from irritation of the os externum, and some time ago had severe hæmorrhoids; has long been subject to rheumatism, sciatica, and much gastro-intestinal derangement, with occasional bilious fever.

Examination per Vaginam.—Os uteri soft and pulpy; cervix hard, especially on the left side; there is also pain in the direction of the left ovary; the os uteri is much congested, with a purple and patchy appearance.

℞ Acidi hydrochlor. dil., acidi nitrici dil. aa. ʒi.; extracti taraxaci, ʒj., infus. aurantii co. ad ℥vjjj. M. ft. mistura cujus sumat; coch. magn. ij. ter die; liq. plumbi diacet. ex decoct. papaveris; hirudines vj. ori uteri.

August 19th.—Leeches have been applied three times since last report; the blood was dark and thick, "almost like treacle;" but little blood came the first time; they bleed freely the second time the last application gave decided relief. The catamenia have appeared twice since last report; the pain, which was of a sharp darting character, came on only three or four days previously; the discharge was scanty, but she thinks its colour improved. Tongue with a deep longitudinal furrow, thickly furred, and with red papillæ at the tip. She thinks that the leucorrhœa is rather less. She still has pain about the sacrum, and the motions are flattened.

Examination per Vaginam.—Os uteri soft and open; rather forwards; fundus inclined backwards; the uterine sound passes 2½ inches in that direction.

℞ Pil. hydrarg. extr. hyosc. aa. gr. v. h. s. semel in septim.

℞ Ferri sulphatis gr. ij.; acidi sulph. dil. ♏ x., magnesiæ sulph. ʒi.; syrupi rhœados ʒss.; aquæ menth. pip. ℥i. M. ft. haust. bis die sumendus. Rep. lotio.

November 11.—Feels better; more appetite; tongue better; motions are flattened, and passed with pain; irritation of os externum less; the leucorrhœa is not better; she has menstruated twice since last report; the discharge came at the night-time, and was of a much better colour; has constant pain in both hips, especially the left. For the last week she has felt freer from pain of back and left groin than she has done for a long time.

Examination per Vaginam.—The os uteri is in its natural position, the cervix softer and less painful.

With the speculum, the os is red and granular at its inner edge; a long rope of whitish mucus was drawn away, and argenti nitras freely applied.

Rep. Pil. mist. et lotio.

℞ Plumbi diacet. extr. Conii. aa. gr. x.; pulv. acaciæ, ʒss. M. ft. suppositorium, ori uteri alternis noctibus applicandum.

Two of the most characteristic symptoms of retroversion, viz., the pain across the back of the pelvis, and the pain of left groin, were prominent features in Mrs. A.'s case; the latter symptom, although so frequently attendant upon retroversion, is not a necessary concomitant; it is one which indicates a result of retroversion, rather than the existence of retroversion itself; it points out the presence of ovarian irritation or inflammation which so frequently attends their displacement, and which, in so large a majority of cases is confined to the left side. When I first noticed the connexion between these two conditions, I believe that the left ovary was affected nineteen times to once of the right, but further observation has since induced me to rate the difference as still greater. I presume that the position of the sigmoid flexure of the colon on the left side may have something to do with it, especially when we bear in mind the liability to fecal accumulation at that part of the intestinal canal.

The pain and irritation of the left ovary, so commonly observed in cases of retroversion, is probably produced by the broad ligament in which the ovary is situated being put on the stretch, and the returning circulation thereby hindered; hence we see that this increased as the catamenial period gradually approached, so that for ten days before each time the pain was considerably aggravated. The uterus in this case relieved itself slowly and with difficulty, but in some instances the ovarian irritation is attended with much dismenorrhœal suffering and exudations, and in others by profuse menorrhagia, of which I will give cases. The constant leucorrhœa which existed during the intervals may be attributed partly to the displaced uterus acting almost like a foreign body in the vagina, and partly to the general gastro-enteric derangement, and consequent engorgement of the abdominal circulation.

It is to this condition in the present case that I would especially direct attention; it was of no recent formation, but had evidently existed for some time, as shown by her attacks of bilious fever, and by the rheumatism and sciatica from which she has suffered; in other words, the history of her general symptoms tended to prove that the uterus had been long subject to an undue amount of pressure from the superincumbent abdominal viscera, whilst the local examination showed it to be more congested, and therefore heavier than natural.

The application of leeches to the os uteri produced much relief; the blood at first was dark and thick, but gradually became more natural; the catamenial discharge improved in colour, and the pains of which she complained were decidedly diminished. The liver was roused by a gentle alterative, while the activity of the bowels was increased by the combination of ferri sulphas with sulphate of magnesia, a form which is well adapted for relieving passive congestion of the abdominal circulation and torpidity of the bowels, &c. The health continued to improve. The os uteri assumed a more healthy and florid appearance; it resumed its natural situation, and, after applying a suppository of plumbi diacetas with extr. conii, I ceased to hear from her.

ON THE VALUE OF THE THERMIC TREATMENT IN VARIOUS DISEASES,

ESPECIALLY IN

CERTAIN FORMS OF NEURALGIA, PARALYSIS, AND RHEUMATISM.

By GEORGE E. DAY, M.D.,
Fellow of the Royal College of Physicians, Physician to the Western General Dispensary, &c.

In the Appendix to my Treatise "On the Diseases of Advanced Life," published last autumn, I detailed a few cases illustrative of the success I had met with in the treatment of various local affections, by the application of a form of counter-irritation, which, although casually noticed by several surgeons and physicians, appeared to me never to have met with the attention from the Profession which its singular value demands. For the want of a better name I have called it the *thermic treatment.* It consists in the instantaneous and repeated application of a small iron hammer, gently heated to the skin. The merit of introducing this form of counter-irritation is due to the late Sir Anthony Carlisle, who, early in the year 1826, published a letter to Sir Gilbert Blane, "On Blisters, Rubefacients, and Escharotics, describing the employment of an instrument adapted to effect those several purposes," and in the November Number of the *Philosophical Magazine* for the same year, addressed a letter to the Editor of that Journal on the same subject. This instrument was for some time used in the Westminster Hospital; but the only information I can obtain regarding the success of Sir Anthony Carlisle's treatment in that Institution is, that he failed to cure two cases of hydrophobia, in which he freely applied it along the spine. In 1829, M. Mayor, (a) of Lausanne, published a Memoir, "Sur la cautérisation avec le marteau," in which he shows, that by an instrument of this nature, the effect either of a mustard-poultice, or of a blister, or even of the moxa may be instantly produced. Both Sir Anthony Carlisle and M. Mayor heated their instruments by immersion in boiling water. This method has been adopted by Trousseau, (a) Harvieux, (b) Vanoye, (c) Kneeland, (d) and others. About three years ago, Dr. Corrigan published (in the *Dublin Hospital Gazette*) a series of cases treated in a somewhat similar manner; he, however, makes use of the flame of a spirit-lamp for the purpose of heating his instrument, which, from the description he gives of it, seems more portable and convenient than those previously employed. The instrument I employ is shorter and more portable than that recommended by Corrigan. It is in reality a small hammer. (e)

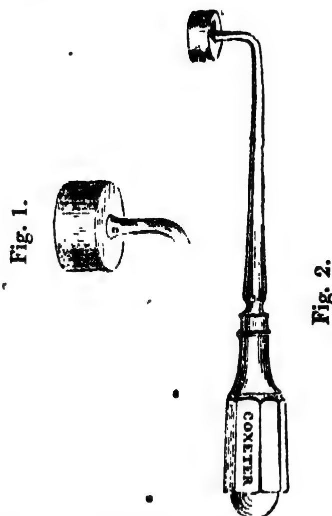

Fig. 1. The actual size of the extremity.
Fig. 2. The whole instrument reduced in size.

Placing the end of the forefinger on its curve, I hold the metallic extremity in the flame of a spirit-lamp for about fifteen or twenty seconds. This is a readier mode of heating it than that adopted by Carlisle. By this time, the finger becomes rather uncomfortably warm, and this I regard as indicative of the instrument being sufficiently hot for my purpose. I run it lightly, alternately raising and depressing it, over the part affected. The whole operation is over in a few seconds, the patients scarcely ever complain of the application being painful, and the slight discoloration of the cuticle, which usually follows, altogether disappears in two or three days.

Being anxious to see if other Practitioners found it equally serviceable with myself, I urged several friends to give it a trial,—amongst these I may especially mention Dr. Adey, Dr. Miller, Dr. Palmer (our late Resident Officer at the Western General Dispensary), Dr. White of Winchester, Dr. Webster of Cambridge, Mr. J. C. Langmore, Mr. Richardson, Mr. C. A. Aikin, and Mr. Webster. I may observe that, for the last year, a day has seldom passed in which I have not applied the hammer on an average two or three times. Moreover, it is constantly used amongst my patients at the Western General Dispensary, where several of my colleagues have seen and borne witness to its success.

As no object would be gained by a multiplication of cases, I shall select a few, illustrating its value in different forms of disease.

I shall commence with cases of neuralgia. The very list of reputed remedies for neuralgic affections

(a) A writer in the *London Journal of Medicine*, in a notice of my book in that periodical, observes, that my mode of treatment is simply that of M. Mayor. Although there is nothing surprising in his ignorance of the subject, yet as all his information on the point seems derived from my Appendix, it is difficult to understand why he should have deemed it expedient to quash the (at least equally strong) claims of Sir A. Carlisle

(a) "*Traité de Therapeutique.*" Troisième ed., Vol. II., p. 517.
(b) *L'Union Méd.*, Nos. 38, 39, 1847.
(c) *Ann. de Flandres*, Mars, 1848.
(d) *American Journal of Medical Science*, Oct., 1848.
(e) I may observe, that the instrument may be seen in Grafton-street East, at Mr. Coxeter's, who has fitted up very convenient pocket-cases, containing the hammer and a small spirit-lamp.

is sufficient to show how difficult they are to remove, and on what various causes they depend. If we open any recent work on neuralgia, we find under the head of treatment nearly every article of the *materia medica*. Arsenious and arsenic acids and their salts, quinine and the salts of iron, opium and the salts of morphia, belladonna, hyoscyamus, datura stramonium, aconite, valerian and the valerianates, ether, musk, castor, sulphate of zinc, assafœtida, camphor, bismuth, oil of turpentine, croton and cajeput oils, are but a few of the medicines which are reputed to have proved successful in the hands of different Practitioners; to say nothing of the many local modes of treatment which have been recommended in the form of lotions, frictions, endermic and epidermic applications, blisters, cauterization, electricity, mineral magnetism, acupuncture, down to division or excision of a portion of the nerve.

I need scarcely observe, that I am far from wishing it to be understood that the thermic treatment will effect a cure in all neuralgic affections. But of this I am fully convinced, that in all cases likely to be relieved by any system of counter-irritation, the thermic treatment is of the greatest value, both on account of the rapidity with which it allays pain, and in consequence of entailing none of that annoyance on the patient, of which we hear frequent complaints, when using blisters, irritating embrocations, &c.

In order to obtain as fair an estimate as I could, of the value of the thermic treatment, I requested the friends I have mentioned, on whose judgment I could fully rely, to try it, and give me their candid opinion regarding its merits; and I have incorporated several of their cases in this paper.

AFFECTIONS OF THE FACE AND HEAD.

Case 1.—Samuel Flower, aged about 30 years, applied at the Dispensary on the 22nd of March. He had been out of employ for many weeks, and had been exposed to cold and wet, his means of obtaining food being very precarious. He had a haggard and anæmic appearance, and I was led to expect the presence of phthisis, a view which was subsequently confirmed by an examination of his chest. The object of his application was to obtain relief for frontal neuralgia of the right side, which he describes as having been most severe since the 19th, when it came on suddenly and for the first time. He had taken purgative medicine, and applied mustard poultices to the seat of pain without the least relief.

I applied the hammer, which instantly removed the pain. *No medicine* prescribed.

24th—No pain in the frontal region since I applied the hammer two days previously; but complains of slight pain in the back of the head behind the right ear. I applied the hammer to the most painful part, which relieved, but did not altogether at once remove the pain. I saw him again on the 29th and on the 10th of April, and found that there had been no return of the pain.

Case 2.—Emma S., aged 20, single, came under my care on 13th March. She presented a generally healthy appearance, and was regular in reference to her bowels, &c. She applied to me in consequence of severe frontal neuralgia of the left side, and of an irregularly intermittent character. These pains had existed for some months, and she had been under the care of several Practitioners. In consequence of the intermittent character of the case she was ordered the quinine mixture three times a day, the bowels being previously well acted on.

17th.—The medicine afforded no relief, the pain being very severe. I applied the hammer to the forehead. On leaving the room a few minutes afterwards, she said she felt nothing more than the tingling produced by the application of the warm instrument.

20th.—Not a trace of pain since the application of the hammer; I therefore did not apply it, but, as a measure of precaution, again put her on the quinine mixture.

27th.—The pain in the forehead returned on the 23rd with considerable severity, and has continued ever since. The hammer was applied to the frontal region, which relieved, but did not entirely remove, the pain.

April 3rd.—The pain was scarcely perceptible till the 30th, when it re appeared, but with less severity. I applied the hammer.

There was no further return of pain, and she was discharged, cured, on the 14th of April.

Case 3.—" John Bunce (a), aged 38, a labourer, was admitted into the Hants County Hospital, under my care, on January 24th, 1849. Three weeks previously, he had been seized, in the evening, suddenly, with a sharp pain in the left supercillary and frontal region, which had continued, with occasional incomplete intermittence, up to the above date.

Present State on Admission.—Bowels not opened for last four days, and are reported to be generally costive. Some nausea and occasional sickness. Tongue very foul. Pulse 60, weak and quiet. Urine reported to be thick. The left eye three parts closed, and constant lachrymation from it. Intense pain over it.

℞. Hydrarg. chlorid., gr. iij.; ext. coloc. c., gr. vi.; ol. croton., ♏ i.; in pilulis hâc nocte. Enema terebinth. statim. Emplast. extract. aconiti supercilio sinistro.

25th.—The injection brought away some scybalous masses. The pills caused vomiting, and, consequently, did not purge him. He states, that the pain is not so rapid."

Ordered—House-diet, with beef-tea instead of beer.

℞. Ext. coloc. c.; pil. aloës c. myrrha, aa. ʒss.; antim. pot. tart., gr. i.; in pil. xii. div. quarum sumat ii. omni nocte.

℞. Mist. gentian. c., ℥iss. omni mane.

28th.—No relief to the pain, although much scybalous matter has been removed. Ten minims of the solution of amorphous quinine were ordered to be given twice a day, in the form of draught, in addition to the previous medicine.

Feb. 2nd.—The quinine has now been taken for four days without benefit. Applied the hammer freely over the painful eyebrow, and the adjacent frontal region. Immediate relief obtained. Ordered to discontinue the quinine, and to take three minims of Fowler's solution in decoction of sarsaparilla, thrice daily.

4th.—The pain has been very slight ever since the application of the hammer. He was, in fact, so much relieved by it as to leave the Hospital on the 9th.

March 3rd.—Attended this day as an out-patient. The pain had returned, but with nothing like its original severity. I again applied the hammer, when he stated himself as freed from all pain.

13.—Has not again presented himself at the Hospital."

In a subsequent letter from Dr. White, I find that this patient is now exhibiting undoubted symptoms of organic disease of the brain. This probably explains the nausea of which he complained on admission, and the extreme constipation. I regard the case as very instructive, showing that, *even when the neuralgic affection is dependent on cerebral disease, great alleviation of suffering is obtained by this treatment.*

The following case produced a great impression on my mind at the time:—

Case 4.—William Cox, aged 45; a servant out of place; came under my care on Nov. 19th; has been a soldier, and spent fifteen years in India, where he had several attacks of dysentery; has been six years in England, during most of which time he has been a gentleman's servant; gave up his last place about two months ago, in consequence of severe pains in the right side of his face.

These pains began the previous March, after prolonged exposure to cold and wet while travelling with his master. He describes them as rapid, shooting pains, of an insupportable character; they partly yielded to medical treatment during the ensuing warm months, but at the commencement of the autumn they returned with their former severity, and he was rendered altogether unfit for work.

His countenance is sallow, and bears the signs of acute suffering. He has comparatively little pain during the day, but about half-past six every evening a darting agonising pain comes on, which he describes as rendering life insupportable. It extends over the whole of the right side of the face, is very severe in the right temple, and proceeds, but with much less severity, towards the top of the head. It seems neither increased nor diminished by pressure over the infra-orbital foramen, or at any other point, although it may be sometimes excited during the day, by simply touching the face, or by a gush of cold air. The mere touch of the bed-clothes would often induce it at night. From prescriptions which he showed me, it appears he has taken iron, quinine, arsenic, colchicum, and iodide of potassium; and besides these medicines he had got into the habit of taking very large doses of opium. A new remedy often gave him relief for a few days, but then seemed utterly inert.

The bowels were constipated (probably, in part, from the opium); the urine was loaded with urate of ammonia; the skin dry and somewhat yellow; the tongue foul; the appetite bad; and, on examining the abdomen, I found considerable enlargement of the liver, unaccompanied, however, with any tenderness.

I ordered a pretty sharp emetic, to be followed next morning by four ounces of infusion of senna, with half a drachm of sulphate of potash, and a scruple of sulphate of manganese, and restricted him to a milk and farinaceous diet. He promises to diminish his dose of opium by one half.

22nd.—The tongue was now almost clean; the bowels had been very freely acted on, the evacuations being well tinged with bile. The pains had been much the same, but he felt better in himself. I saw him about three hours before the period at which the paroxysm usually came on, and applied the hammer freely over the right cheek and temple. The application did not excite the nervous pain, and gave him no annoyance in any way. I prescribed nothing but a little aperient medicine, to be taken daily.

23rd.—There was no pain whatever till between nine and ten o'clock last night; that is to say, the access was totally retarded for three hours; and it was then much slighter; more, in fact, like the occasional pains felt during the day. Applied the hammer as before.

I need not follow out all the particulars of this case, as noted down at the time. In the course of a week, the opium was altogether dispensed with.

The hammer was applied seven times in all, at intervals of two or three days; and I gave him, on the 30th, a mixture of iron and quinine, taking care only to regulate the bowels.

Dec. 14th.—He called to thank me, and to report himself as well as ever he was in his life. I saw him once afterwards, some time in January. He came to tell me he had got a situation, and was going to leave London. There had not been the slightest relapse. I desired him to write to me if there was any return of the pain; but I have not heard from him.

The treatment of this case differs from that in the previous ones, in the fact of the hammer being applied at times when there was comparatively little pain; that is to say, before the paroxysms.

I might give several other cases, although less marked than that of Cox, in which the thermic treatment has afforded relief, after numerous other means have altogether failed.

For notes of the following and several similar cases, I am indebted to the kindness of Dr. Palmer, our late resident medical officer.

Case 5.—Mrs. Gallop, aged 30, applied for relief at the Western General Dispensary, on the 28th of March, in consequence of neuralgia of the left temple. The hammer was applied, which at once relieved the pain; tonics were also prescribed.

April 2nd,—There has been no return of the pain.

Case 6.—Mrs. Clarke attended the Dispensary on April 26th, in consequence of an attack of hemicrania.

(a) For this case I am indebted to Dr. White, Physician to the Winchester Hospital.

The pain was at once relieved by the application, and did not return for two days. I am not in possession of any further notes regarding this patient.

In the following cases the reason of the failure is tolerably obvious.

Case 7.—Frances Preston, aged 48; entered under the care of Dr. Miller, at the Western General Dispensary, on the 27th of March. The case is copied from notes with which he has obligingly favoured me.

"Sallow and cachectic; has not menstruated for four years; hysterical; has been the subject of inveterate neuralgia of the face and neck for more than a twelvemonth. Neuralgia of the fifth on the right side, and of several branches of the cervical plexus. She obtained some relief from quinine and morphia, but it was not permanent. The hot iron was applied on the 3rd of April, which afforded some relief to the neck; pain still severe about the face. The iron was again applied on the 5th and the 10th, with a slight temporary relief, and I believe once subsequently. She prefers the local application of belladonna, and I cannot get her to try the hot iron again. I believe that in this case there is some disease of that portion of the skull through which the branches of the trifacial on this side pass."

I fully concur in Dr. Miller's view, that there is disease of the bone in this woman; a view much strengthened by her having recently had a sanguineo purulent discharge from the nostrils.

I may add, that last week (July 19th) she voluntarily applied to me, with Dr. Miller's full concurrence, to use the hammer. It afforded considerable instantaneous relief. Leeches to the temple were also prescribed by Dr. Miller. On the 26th, she again appeared, having spent a week of comparative ease. How far the leeches alleviated the pain I cannot say. She, however, attributed the relief to the hammer, and, at her request, I again applied it.

I shall now give a few cases, in which the thermic treatment has been tried in *facial paralysis* (paralysis of the portio dura).

Case 8.—For much kind and valuable assistance in this case I am deeply indebted to Dr. Watson and Mr. Dalrymple. G. E. D., a Physician practising in London, had been for some time under the care of Mr. Dalrymple for an obscurity of vision affecting the left eye. On the night of the 17th of January he travelled a long distance in a railway carriage, with his right cheek for some time near an open window, but did not perceive any draught or current of air. On the following morning he felt a very slight degree of tension in moving the lips, and the right eye (the one usually unaffected) became every now and then irritable, and apparently covered with a film. These, and the other ordinary symptoms of facial paralysis, then regularly set in, and increased in intensity till all power over the muscles of the right side of the face, supplied by the portio dura, was completely lost. The most distressing symptom was the impossibility of moving the right eyelid, a dimness being continually present, which was only removable for a few seconds at a time, by pressure on the globe. On the 20th, Mr. Dalrymple proposed that Dr. Watson should be consulted [illegible] a week or two [illegible] previously to the attack, there had been severe and prolonged vomiting, intense vertigo, and other symptoms indicative of mischief within the cranium. Taking into consideration these previous symptoms (and, even at this period, there was still considerable vertigo), Dr. Watson and Mr. Dalrymple prescribed one-twentieth of a grain of bichloride of mercury to be taken with compound tincture of bark three times a day, and an open blister behind the right ear. This treatment was steadily persisted in for about ten days, with not the slightest alteration in the state of the face, although with considerable improvement in the general health. Mr. Dalrymple, who had been reading the cases recorded in the Appendix to my treatise "On the Diseases of Advanced Life," suggested that the hammer should be applied, as directed by me. The suggestion was at once adopted, and the hammer applied twice daily. On the first evening (after only two applications) the power of closing the right eye was restored, and, in the course of a week, every trace of paralysis had disappeared.

Case 9.—Mr. W. E., aged 47, had an attack of paralysis of the portio dura of the right side, in March, 1843, after travelling outside a coach, and being exposed to rain the whole day. Various remedies, of which, however, he cannot give a very accurate account, were tried, but electro-magnetism was the first that proved serviceable. Under this remedy the paralysis entirely disappeared in the course of the ensuing summer; but, since that time, any exposure to cold or wet is liable to bring on involuntary twitchings of the muscles originally affected, which usually last five or six days, and then gradually disappear. To use his own expression, "he looks as if he were performing a series of very exaggerated winks."

A single application of the hammer immediately arrests these attacks. He now applies it himself, whenever he feels the peculiar stiffness of the cheek which always precedes them.

These cases occurred in my own practice. The next occurred under the care of my friend, Mr. Richardson, and I am indebted to him for the following notes of it.

Case 10.—M. W., a married lady, aged 40, extremely nervous, was seized during the night of Wednesday, April 25, 1849, with paralysis of the portio dura of the right side. On seeing her on the following morning, about nine o'clock, I found the face much disfigured. She complained of a dead feeling in the right cheek. Pulse 74, tongue loaded, bowels confined, no pain in the head. I applied the hammer over the whole of the affected side, and ordered some aperient medicine.

27th.—She felt the face more comfortable, the feeling of deadness in the affected part was less, but there was no improvement in her appearance. Hammer re-applied.

28th.—Decidedly better, and her appearance more natural. From this time she daily improved under the use of the hammer, till the 5th of May, when, as there only remained a slight stiffness of the muscles of the right side of the face, no further application was made.

In this case, no treatment was adopted but the use of the hammer, with an occasional aperient to regulate the bowels.

Mr. Richardson has given me the particulars of another case of facial paralysis, in which "mercury to the extent of salivation, colchicum, purgatives, counter-irritation, galvanism, &c., were used, without producing the slightest improvement," and where the hammer was ultimately "employed every day for a fortnight, but without any good result." He adds, however, that "the cause of this paralysis was probably of an organic nature, and therefore no benefit could be expected from any mode of treatment."

SCIATICA AND LUMBAGO.

I shall now give, as briefly as I can, a few cases of sciatica and lumbago, which are often associated affections. I have notes of a very considerable number of cases in my own practice, and I have been favoured with the particulars of other cases by Drs. Miller, Palmer, and Webster of Cambridge, and Messrs. Richardson, J. C. Langmore, Webster, Aikin, &c. &c.

I have never met with a case of sciatica or lumbago, however severe or chronic, which was not much relieved by the thermic treatment.

Case 11.—Charles Pope, aged 41, a carman, presented himself at the Dispensary on the 5th of April, suffering from intense lumbago and sciatica of the right side, extending to the calf. He could not take off his coat, or sit down without assistance, and stated, that even the passage of flatus or fæces from the bowels, caused much pain. Was much exposed to cold and wet about six months ago, and for the last five months he has never been free from pain for forty eight hours together. During the last three days the pain has been extremely aggravated, entirely preventing sleep. Dr. Adey (whose valuable assistance in testing the importance of this treatment I gladly take the present opportunity of acknowledging) applied the hammer freely over the whole seat of pain. He did not feel any instantaneous relief, but, on the 7th, (two days subsequently,) told us that the pain had very much abated, directly after leaving the dispensary, and that it was now *quite gone from the loins and thigh*, and that the only remaining trace of his ailment was a dull, aching, sensation in the calf. The hammer was applied there.

10th.—No pain worth speaking of in the calf, and none whatever in his loins and thigh since the first application. I again applied the hammer to the calf. He had returned to work the previous morning, and could walk without the slightest inconvenience.

Case 12.—Mary H., aged 27, applied as a morning patient at my house, on the 26th of June. She had great difficulty in walking into my room; was bent very much forward, and, when she finally contrived to seat herself, informed me,—and her statement was obviously true,—that any movement of the body gave her intense pain. She stated, that she was perfectly well till about five months ago, when, shortly after her confinement, she caught cold, and had an attack of rheumatic fever, for which she was under the care of a highly respectable surgeon in this neighbourhood. She was confined to her bed for two months. When the acute symptoms had disappeared, she had still very severe pains, especially in her shoulders, loins, hips, and knees, totally incapacitating her from following her household duties, and preventing her even from dressing herself. The gentleman referred to recommended that she should become an in-patient in one of the hospitals, and use vapour-baths. She accordingly entered St. George's, where she remained nearly three weeks, without any relief. She was not allowed vapour-baths, in consequence of her debilitated condition; and she was rapidly losing flesh. It is now about ten days since she returned home in a very desponding state.

On examining her chest, I find she is in an advanced stage of phthisis.

As the pains in the arms, shoulders, and between the scapulæ, were the most severe, I resolved to try to alleviate them first.

I carefully observed her while the clothes about the upper part of the chest were being removed, and saw that any motion of upper arm and shoulder gave rise to extreme agony. Even the slight motion required for needlework was unbearable.

I applied the hammer very freely, warming it twice, over the shoulders, between the scapulæ, and along the arms. I then desired her to try to raise the arms. She tried very cautiously, and obviously expecting to be, as before, checked by the pain. The arms gradually rose till she clasped her hands together above her head. The poor woman burst into tears at finding the power of her arms thus suddenly and unexpected restored to her. When she became a little more composed, I made her try to move them in various directions, which she found no difficulty in doing. She fastened the back of her dress without the slightest assistance, which she had not been able to do since the commencement of her illness; and left me, promising to attend again in two days, when I was to apply the hammer to her loins and thighs.

I may, perhaps, be allowed to state, that I was so struck with the suddenness and completeness of the relief afforded to the poor suffering woman, that I requested a lady, who happened to call at my house at the time,—an old and much respected patient of mine,—to see the woman before she left. This lady has kindly permitted me to refer to her, should any of my readers suppose the above account in the slightest degree overdrawn.

June 28th.—This day I applied the hammer very freely and extensively over the loins, down both thighs, and over both knees. Great relief was afforded; she was able to walk with considerably more freedom, and with little pain. She can still move the arms without the slightest pain, but complains of their being somewhat stiff.

July 5th.—She has now a feeling of stiffness and occasional aching, (especially at night,) but no pain worth speaking of. I applied the hammer to the points where these sensations were most marked.

I have since seen her three or four times; there

has been no return of the pain, but she is sinking fast from the pulmonary affection.

Case 13.—James Simpson, aged 38, a coal-porter, applied at the Western General Dispensary on July 7th, for sciatica of both thighs, extending nearly to the knees. It commenced without any apparent reason seven years ago; and he states that he seldom passes many weeks without an attack, which is readily induced by much fatigue, by cold, wet, or an east wind.

Six years ago he was in St. George's Hospital under Mr. Keate, and was cupped, blistered, &c., with no benefit. He has since been under many practitioners with little or no benefit. At present there being very considerable pain, the hammer was applied by my friend Dr. Adey. The pain instantly disappeared.

10th.—No return of pain. 19th.—Ditto. I have not seen him since; but doubtless should have done so if there had been any relapse. This is one of the cases where *a single application* sufficed to effect a cure.

Case 14.—Thomas Sturdy, aged 76, applied at the Dispensary on the 30th of June, for pain extending from the loins to the knees. Had suffered from paralysis agitans for many years, and five years ago had a fit, which was followed by loss of power of the right side, which persisted for some time. He had been in the hands of numerous practitioners, partly for the pains and partly for the paralysis agitans. The hammer was applied on the loins, it being there that he said the pain was most severe. He experienced immediate relief.

July 5th.—Pain in the loins very trifling; that in the hips and thighs very severe. Hammer applied on hips, thighs, and loins, causing a total and immediate removal of the pain. I have seen him since, but there has been no necessity for again applying the hammer.

Case 15.—Abel Barry, aged 37, a plaisterer, applied at the Dispensary on the 10th of April. He states that he has been subject to lumbago and sciatica of the right leg for the last twelve years, the pain extending as far as the knee. On the 4th (six days ago) he was suddenly attacked with excruciating pain while at work, and had to be helped home, being utterly unable to walk. Since then the pain has been continuous, and has prevented him from having any sleep. The hammer was applied to the loins and along the course of the right sciatic nerve, and gave immediate relief.

12th.—Since the application on the 10th, the pain has been very trifling; in fact, there has been only an occasional feeling of aching, and, to use his own words, "he feels quite a different man." I applied the hammer to the spots where he had felt the aching.

17th.—No return of pain. Dismissed.

For the notes of the following case, I am indebted to Mr. Richardson:—

Case 16.—"C. R., aged 54, sent for me on the the morning of the 27th of March, to see him on account of a severe attack of lumbago. He was subject to such attacks, and was generally confined to his bed for three or four days by them; and it was commonly a fortnight before all uneasiness subsided. He stated, that this attack was more severe than usual. I found him in bed, lying on his back, with his legs drawn up, incapable of moving in the slightest degree, without the most intense suffering. The pain was confined to the back; pulse 72; tongue tolerably clean; bowels open. I applied the hammer to the back, which caused the pain entirely to disappear, and, to his great astonishment, he was able to get out of bed by himself, and walk about the room without any difficulty. He was merely ordered some aperient medicine.

"28th.—Has had no return of the pain, and feels quite well.

"29th.—Still continues free from pain. Discontinued my attendance."

I am also indebted to the same gentleman for the following case:—

Case 17.—"S. W., aged 24, awoke during the night of Wednesday, the 21st of March, with violent pains in the back. As the pain continued very severe, I saw him about nine o'clock on Thursday morning, the 22nd. He was in bed, lying on his back, and could not move without suffering great pain. No fever; pulse 72; bowels rather confined; tongue rather loaded. I applied the hammer, which relieved him so much, that he could move with comparative ease. Ordered some aperient medicine.

"23rd.—Much better; perfectly easy when quiet, though some pain is still felt on moving. Bowels freely opened. Hammer again applied.

"24th.—Still some pain on motion, but decidedly easier than yesterday. The hammer was used, as also on the mornings of the 25th and 26th, when, the patient being free from all pain on motion, it was discontinued."

In a note appended to these cases Mr. Richardson adds, "I have used the hammer in three other cases of lumbago with equal success; but, as the symptoms were similar to those in the foregoing cases, I have thought it needless to enter into particulars."

For the report of the following cases of lumbago I am indebted to my friend Mr. Langmore of Upper George-street, Portman-square:—

Case 18.—"Mrs. T., aged 62, a laundress, applied on the 1st of February, stating, that last June she 'ricked' her back, by suddenly lifting a weight, and that a fortnight subsequently she had an attack of lumbago, with pain and a sense of coldness down the left leg. This pain has continued ever since, with occasional exacerbations and remissions. She suffers chiefly at night, when moving in bed. The hammer was applied across the loins and along the course of the left sciatic nerve, and the bowels being torpid, a couple of aloetic pills were ordered to be taken on alternate nights.

"8th.—Has felt less pain during the night, and can 'get about' better in the day. The hammer was applied. There was no return of pain for a fortnight, when, in consequence of a slight relapse, she again desired to have the hammer applied. She has made no complaint since that time."

I regret that want of space prevents me from doing more than making a selection from the numerous cases with which my friends have obliged me.

The following note will convey to the reader an idea of the value attached by Dr. Miller to the thermic treatment. I think that some of the cases recorded above will show that he hardly gives it due credit in pure neuralgia. In two of the cases (Cases 3 and 7,) there is no doubt that it afforded great temporary relief, although the pain was due to structural disease:—

"40, Welbeck-street, July 6, 1849.

"My Dear Dr. Day,—You ask me for the notes of all the cases in which you have applied the hot iron for me at the Dispensary, as well as my opinion regarding the cases in which that mode of treatment seems the most serviceable.

"I subjoin seven cases from my note-book. They are taken, as they were presented to both of us, indiscriminately. In all painful local affections, the result of exposure to cold apparently, the use of your hot iron seems a very valuable remedy. But in cases of pure neuralgia, not resulting from exposure, but from deeper-seated constitutional causes, I cannot say I have seen much good derived from its use.

"Believe me, yours very faithfully,

"Dr. Day." "JAMES MILLER.

The following case occurred in the practice of my colleague, Dr. Miller, and I am indebted to him for the notes of it.

Case 19.—"William Franklin, aged 45, applied to me on the 1st of March. Has sciatic pain, in consequence of sitting in wet clothes. Pain commences near the great trochanter on the left side, passing down the outer side of the limb. Cannot walk without great difficulty. Is a rheumatic subject. The hot iron was applied by Dr. Day. A little relief immediately followed its application.

"March 3rd.—Pain extends now to the foot; the iron re-applied. Immediate relief experienced.

"8th.—Wholly free from pain. Walks with an awkward gait only."

It is needless to multiply cases, when the treatment and the results following it are so uniform. I shall conclude the present memoir with

Case 20.—The case of Mr. K. W., a Polish gentleman sent to me by Sir James Clark. He is an artist by profession. Has lived freely, and suffered by it. Eight years ago, when in the south of France, whither he had repaired for the benefit of his health, he sprained his left foot, and suffered pain and weakness in the joint for upwards of two years. Four years afterwards he was sitting down on the grass, and on rising he felt such great pain in the left leg and hip, especially in the vicinity of the old strain, that he had to be carried home from the spot where he had been sitting. Six months subsequently, and when he had not altogether recovered from the above mentioned attack, he was seized, when rising from the prone position, with a violent pain in the loins, to which were speedily super-added the previous pains in the left leg and hip, and pain of a less violent character in the right thigh and leg. This state of things has now continued for upwards of two years, constituting a very severe case of lumbago and double sciatica. Has gone through all the ordinary remedies without any permanent relief.

I first saw him early in June, when I applied the hammer freely over the loins, hips, and thighs. He experienced little or no immediate relief, and was directed to call again in three days. On his second visit he informed me that he felt decidedly better; the pain was far less acute, and not troubling him at night as it used to do. I applied the hammer, and continued to do so at intervals of four or five days, for three weeks, when the acuteness of the pain was altogether gone, and I permitted him to go to a watering place on the south coast, where he had a professional engagement.

REMARKS ON THE OFFICE OF THE COCHLEA, AS THE SPECIAL ORGAN FOR THE MENTAL DISCRIMINATION OF THE PITCH AND AGREEMENT OF MUSICAL SOUNDS.

By J. D. MACDONALD, Member of the Royal College of Surgeons of London.

(Concluded from page 71.)

The effects of sound shall next occupy our attention in connexion with the physiology of the cochlea. When sounds fall on the outer ear, they are collected by the auricle, and conveyed along the meatus auditorius to the membrana tympani, the conically depressed surface of which seems further to concentrate them, and transmit them to the chain of ossicles by which they are conducted to the internal ear, and thus impinge on the nerves of the vestibule, where, no doubt, the intensity of sounds is felt, and on those of the semi-circular canals, where, perhaps, their distance and position are appreciated. But what more immediately concerns us is, that a portion of the sonorous vibrations passes along the scala vestibuli, (as we suppose, for the analysis of pitch,) which, after having reached the cupola, probably descends by helicotrema, for some distance in the tympanic scala. This we may term the primary or direct current of sound, to distinguish it from another, which is of a secondary character, and in part derived from the former. This current is formed by the vibrations of the ossicles and parts connected with the tympanum, communicated to the air in its cavity, and transmitted through the membrana fenestræ rotunda to the scala tympani. In the scala tympani it meets with the primary one, which we have traced to this locality. Now, without straining any fact which may naturally exist, or laying down groundless suppositions to establish a theory, it appears clear, that, by following the course which sounds appear of necessity to take, agreeable to the physical structure of the parts of the organ of hearing, a collision of two currents of sonorous undulations takes place in the scala tympani of the cochlea where the nerve is spread out to receive the impulse thus excited; and if the particular locality in the scala where the collision of those currents takes place, is regulated by the pitch of the sound composing them, it does not seem unfair to infer, that there is a certain spot on the expansion of the cochlear nerve where each note is duly appreciated by the mind, the very arrangement of the fibrils of the nerve itself would

indicate the position; for, in proportion as the little bundles which they form approach the apex of the coil, they diminish in size; so that they may be said to hold a certain relation with the pitch of the sounds impinging upon them.

As the membrana fenestræ rotundæ has no muscular apparatus adapted to it, whereby its tension may be modified, we may infer, that, independent of the action of the membrana fenestra ovalis, the sonorous vibrations transmitted through it to the scala tympani can never be altered in their effect, while their qualities remain the same as to their strength of tone and particular pitch. But the membrana fenestra ovalis being firmly connected as it is with the ossicula auditus, must suffer considerable change in its vibratile properties from corresponding alterations in its tension effected by the action of certain muscles which draw upon the ossicula, and thereby upon the membrane. The same chain of bones being employed, though as passive organs, in the adaptation of the membrana tympani to the sounds impinging on it, manifests a unity of design and function between the latter membrane and the membrana fenestra ovalis, although their positions and connexions being different must call for the performance of offices peculiar to each.

The fenestra ovalis, then, being the inlet of sounds passing to the scala vestibuli, it would appear that the tension of its membrane, or the pressure which the base of the stapes exerts through it on the perilymph, is exactly adapted to the pitch and quality of the tones entering to the nerve, at least within a certain range, while the membrana fenestræ rotundæ being passive does not alter the vibrations passing through it, except by the operation of the membrana fenestra ovalis, for the latter indirectly acts upon the former through the medium of the perilymph; thus the same change which modifies the current of sound in the vestibular scala is found also to affect that in the scala tympani. This has been demonstrated by Weber, although in quite another way, and it seems intimately connected with the localizing of impressions. It is probable that the cochlear muscle, lately put forth in its true light in Dr. Todd's and Mr. Bowman's Physiology, exerts its influence in the adaptation of the nerve to particular sounds, both as it regards their intensity and quality of pitch, if the above views be correct. It may be brought into play where the nerve is percussed by the meeting of the currents aforesaid; but the *modus operandi* does not appear very manifest, whether by contraction or relaxation. Even waving the doctrine of a collision of the sonorous currents, by their simple crossing in the scala tympani, the impression upon the nerve is, in effect, doubled, and there is also ample provision made for the physical operation of the law of interference, so that the mind may be impressed with the agreement or disagreement of two or more sounds according as their undulations may, or may not, correspond.

In connexion with the doubling of the impression just noticed, it may be added, that the capacity of the coiled tube of the cochlea as a closed acoustic instrument (of about one inch and a half in length, and having a diameter of one-tenth of an inch at the base, and one twentieth at the apex) may be estimated at double that which its measurements would indicate, were it at all open, as is shown by a circumstance that has hitherto escaped the observation of physiologists.

It is well known to scientific musicians that any open organ pipe can be made to sound its octave, or eight notes below, by stopping the end of it, thus, —E on the fourth space becomes equivalent to E on the first line, and this constitutes the difference between the open and stopped diapason. The former affording a free outlet to the air at its extremity, while the latter being closed, confines it, and causes a retrograde current of sound to take place in the pipe, which seems to produce the deep note of the octave. Now, this principle of the stopped diapason is closely adhered to in the general arrangement of the cochlea; yet, it not only consists of a closed tube, but the retrograde current which takes place in the scala tympani, when the sound reaches the cupola from the vestibular scala, is separated by the spiral lamina from the primary current in the latter scala, and thus a more perfect structure is formed (a hint to organ builders.) And, again, instead of the sound passing off by an opening, as it does eventually in the stopped diapason pipe, the retrograde current is met, as above explained, by the vibrations which the membrana fenestræ rotundæ transmits from the cavity of the tympanum to the tympanic scala. On the supposition that the small membranes of the labyrinth, if separated from the organs, would perform some multiple of the number of vibrations constituting any sound impinging on them, it is not improbable that this rapid vibration may be diminished to a considerable extent, but in the proper ratio, by the last-mentioned arrangements, so as to approach nearer to the characters of the original sound.

REMARKS, STATISTICAL AND GENERAL, ON TRANSFUSION OF BLOOD.

By C. H. F. ROUTH, M.D.,
Physician to the St. Pancras Royal General Dispensary.

My attention having been lately called to the subject of tranfusion of blood, in consequence of my having resorted to that plan of treatment in a case of cholera (see *Lancet*), I was led to collect together in a tabular form all the recorded cases in which this operation had been performed, with a view of coming to something like a definite result upon the expediency of it, and the cases in which it should be practised. For, much as is due to Messrs. Blundell, Waller, and Doubleday, for the vast amount of information, chiefly physiological however, on this subject, still deductions made on any extensive set of cases on the human subject are a desideratum. I think the facts herein embodied are such as to justify the more general practice of this operation in many cases which have hitherto been considered hopeless. I must admit, I was quite unprepared for the conclusions to which the investigation of this subject has brought me, I presume others will be equally surprised on their perusal. In this manner I have thought that it would not be altogether without interest to bring the subject before the Profession.

The following is a List of all the recorded cases which I have been able to collect, and in which I have endeavoured to embody some of the most important points connected with the operation:—

FORTY-EIGHT CASES IN WHICH THE OPERATION OF TRANSFUSION OF BLOOD WAS PERFORMED, WITH A SHORT SUMMARY OF EACH CASE, AND THE RESULT OBTAINED.

1. THE MORE ANCIENT CASES.

No. 1.—Reported in the "Philosophical Transactions," Vol. II., by Messrs. Lower and King; a healthy man. Twelve ounces of arterial blood were taken from a sheep, having been first received in a vessel, from which quantity 6oz. were transfused. Subsequently a direct communication by means of a quill being established between the artery of the sheep and the vein of the man, other 6 oz. were transfused. No ill effect resulted.

No. 2.—Reported in the "Philosophical Transactions," Vol. II., by Mr. Denys; a lethargic young man. The blood from the artery of a sheep was again transfused in this case with the effect of sharpening, it is said, his wits!

No. 3.—Reported in the "Philosophical Transactions," Vol. II., by Mr. Denys; the same person. The operation being repeated on another occasion, he died.

No. 4.—Reported in the "Philosophical Transactions," Vol. II., by Messrs. Denys and Emery; mania; aged 34. This patient was first bled to 10 oz., and 6 oz. from a calf were transfused. He was better next day, when a second transfusion was practised, and 1 lb. of calf's blood injected, when, complaining of suffocation, it was suspended. He got better. Some weeks after, however, he got worse, and the Medical men would not repeat the operation. He subsequently died.

2. THE MORE RECENT CASES.

No. 5.—Reported in the "Physiological Researches," by Dr. Blundell; uterine hæmorrhage. In this case respiration ceased six or seven minutes after the Doctor's arrival. The blood obtained from two males was easily injected, but no resuscitation followed.

No. 6.—Reported in the "Physiological Researches," by Dr. Blundell; bursting an artery. This was a case at Guy's Hospital, a patient of Mr. Key's. The operation of transfusion was not performed till three or four minutes after cessation of respiration. No resuscitation followed.

No. 7.—Reported in the "Physiological Researches," by Dr. Blundell; puerperal fever. Symptoms of prostration occurring, the operation was performed; 6 oz. obtained from the father being injected. No obvious effect was produced. She ultimately died of the fever.

No. 8.—Reported in the "Physiological Researches," by Dr. Blundell; uterine hæmorrhage. 3 or 4 ozs. only could be obtained from a young lady for transfusion in this case. This was injected before respiration ceased, but was not sufficient to produce resuscitation.

No. 9.—Reported in the "Physiological Researches," by Dr. Blundell; obstinate vomiting; aged 35. This was a patient of Dr. Cholmleys at Guy's Hospital. The operation was performed by Messrs. Blundell and Cline. He rallied the first thirty hours after the operation, but then sunk again, and finally died fifty-six hours after the operation. In this case, however, scirrhus of the pylorus was found after death.

No. 10.—Reported in the *Lancet*, 1825-6, Vol. IX., p. 111; Mr. Doubleday's first case; uterine hæmorrhage. In this case the blood was furnished by the husband. Recovered.

No. 11. Reported in the *Lancet*, 1825-6, Vol. IX., p. 154, by Mr. Waller; uterine hæmorrhage. In this case, after the transfusion of 9 oz., the patient completely rallied. It was feared, however, in consequence of her previous debilitated state of health, she would ultimately die, but not by reason of the transfusion.

No. 12.—Reported in the *Lancet*, 1825 6, Vol. IX., p. 782; Mr. Doubleday's second case; uterine hæmorrhage. This patient was completely insensible when the operation was performed, and did not rally.

No. 13.—Reported in the *Lancet*, 1825-6, Vol. IX., p. 295, by Dr. Uwin; uterine hæmorrhage. From 1 to 1½ hours after the expulsion of the placenta, hæmorrhage supervened; 6 hours after, transfusion was practised; 6 oz. taken from Mr. Wright were transfused. She rallied, but sunk again, when 6 oz. more, taken from Dr. Uwin, were injected, and she completely recovered.

No. 14.—Reported in the *Lancet*, 1826-7, Vol. II., p. 457, by Mr. Brown; uterine hæmorrhage; aged 30. This was a lady of delicate health. The operation performed by Messrs. Waller and Doubleday. Recovered.

No. 15.—Reported in the *Lancet*, 1828-9, p. 232; Mr. Dieffenbach's first case; hydrophobia. This patient did not recover.

No. 16.—Reported in the *Lancet*, 1828-9, p. 232; Mr. Dieffenbach's second case; asphyxiated child. This child was still-born. On injection of the blood he moved a little, but did not finally recover.

No. 17.—Reported in the *Lancet*, 1828-9, p. 432, by Dr. Blundell; uterine hæmorrhage; aged 25. Assisted by Messrs. Davis, Pointer, and Lambert. The hæmorrhage was stopped but such weakness supervened, that transfusion, was practised; Mr. Davies supplying the blood. She quite recovered.

No. 18.—Reported in the *Lancet*, 1827-8, Vol. I., p. 662, by Mr. Clement; uterine hæmorrhage. In consequence of a miscarriage; 15 oz. obtained from a healthy man transfused. Quite recovered.

No. 19.—Reported in the *Lancet*, 1827-8, Vol. I., p. 698, by Messrs. Howell and Ravis; uterine hæmorrhage before labour; aged 40. On March 31, at half-past three o'clock, sent for; found the patient flooding. The membranes were ruptured, and hæmorrhage stopped. At six, sent for again; slight labour-pains and flooding noticed; very cold surface and pallidity. 3 oz. of brandy given without effect. Mr. Ravis called in, agreed on the propriety of transfusion. Mr. Doubleday called in; collapse complete. 12 oz. of blood cautiously transfused. She rallied after the injection of 5 oz., when pulse was perceptible, and the body warm. Still-born child expelled one hour after transfusion.

No. 20.—Reported in the *Lancet*, 1829-30, p. 369, by Mr. Green; compound fracture of tibia, secondary hæmorrhage, and amputation. The secondary hæmorrhage came on ten days after the accident; subsequently amputation was performed. The operation of transfusion was twice performed, 8 oz. on the first, and 10 oz. on the second occasion. She finally died, and Dr. Blundell who saw her opined there was some other cause of death.

21. Reported in the *Lancet*, 1830-1, Vol. I., p. 50, by M. Roux; secondary hæmorrhage after a gun-shot wound. The wound was in the right shoulder; the bone minutely fractured. On the

25th day secondary hæmorrhage came on; it was arrested for one week, but returned, when the subclavian was tied. The hæmorrhage continued, with some symptoms of pleuritis; the patient was much exhausted; transfusion was practised; 10oz. were injected, when suffocation came on and he died. In the *post mortem*, the heart and left subclavian were found filled with clots, and the left lung contained small abscesses.

22. Reported in the *Lancet*, 1834, Vol. V., p. 156, by Dr. Klett, 1st. case; uterine hæmorrhage; aged 41. Slight hæmorrhage had continued eighteen hours after delivery, when Dr. Klett was called in. Collapse was then present; the astringents and excitants given had no effect; ℥ij were transfused, the blood being taken from a healthy male. The patient rallied, and under the use of tonics recovered completely.

23. Reported in the *Lancet*, 1834, Vol. V., p. 156, by Dr. Klett; 2nd case; uterine hæmorrhage; aged 31. This case closely resembled the last. Complete recovery here also resulted.

24. Reported in the *Lancet*, 1834, Vol. V., p. 924, by Messrs. Healey and Fraser; uterine hæmorrhage; aged 40. This patient was frequently subject to pulmonary attacks. She was delivered of her tenth child by a midwife; the placenta retained, and intense hæmorrhage followed; Dr. Healey called in. Complete collapse; no pulse; cold; intellect clear. Dr. Fraser called in. Placenta partly adherent, not removed, as it was thought such an attempt would be fatal; 4 oz., taken from the husband, transfused; she quite rallied, and, subsequently, the placenta was removed. Cure complete.

25. Reported in the *Lancet*, 1842-3; Westminster Hospital case. Particulars not stated, but the patient recovered.

26. Reported in the *Lancet*, 1839-40, Vol. II., p. 871, by Mr. May; uterine hæmorrhage; aged 29. Slight hæmorrhage had persisted off and on for two months, continuing after quickening. Mr. May sent for, and found a placenta previa; secale cornutum given; fœtus expelled next day; much hæmorrhage supervened. Dr. Cowan and Mr. Harris called in. Collapse then complete; transfusion practised; 2½ oz. blood taken from four males transfused. Placenta expelled next day; she rallied quite, but secondary hæmorrhage came on five days after, of which she died. No signs of phlebitis were observed after death.

27. Reported in the *Medical Gazette*, Vol. XIV., p. 599, by Mr. Bickersteth; uterine hæmorrhage; aged 30. Fourth child; eight months gone; 27th August in labour pains; os uteri not dilated; opium given. 28th. In strong labour; delivered of a stillborn child; placenta came away immediately; hæmorrhage supervened. Mr. Blackburn called in. Cordials given; patient cold and clammy; pulse just sensible; answered questions, but did so unconsciously; 10 or 12 oz. transfused. Cure complete.

28. Reported in the *Medical Gazette*, Vol. XVI., p 480, by Mr. Turner; medullary sarcoma of knee, amputation; aged 37. Female; Sussex County Hospital. Thigh amputated; femoral veins being much enlarged, much hæmorrhage followed succeeded by collapse; 5 oz. from a gentleman present transfused; rallied; stump healed. Cure complete.

29. Reported in the *Journal of American Medical Science*, Vol. VII., 1830, p. 255, by Dr. Savy; uterine hæmorrhage; aged 36. Third month of gestation; transfusion practised, and cure complete.

30. Reported in the *Journal of American Medical Science*, 1827-8, Vol. I., p. 229; Vol. IV., p. 430, by Mr. Douglas Fox; uterine hæmorrhage. A six months fœtus expelled; placenta retained through an hour-glass contraction; hæmorrhage arrested, but collapse followed. She rallied completely on the transfusion of about a common teacupful of blood. Recovered completely in three weeks.

31. Reported in *Forbes's Medical Review*, Vol. XI., p. 263, by Dr. Richard Oliver; uterine hæmorrhage. The blood was obtained from three neighbours; 12 oz. were then injected; she rallied upon this; finally, 24 oz. in all were transfused.

32. Reported in "L'Experience," Vol. VI., p. 41, by Mr. Lane; hæmorrhage after strabismus. In a case of hæmorrhagic diathesis, where the operation for strabismus was performed, hæmorrhage continued for six days, when, by reason of the collapse, 5 oz. were transfused gradually; subsequently, 10 or 12 oz., obtained from a female. The recovery was slow but complete.

33. Reported in the *Medical and Provincial Journal*, by Drs. Prichard and Clarke; atrophy from dyspepsia. The dyspepsia in this case had been an early symptom. At the time of the operation urine was depositing large quantities of chyle and lithates; all attempts to take nourishing food failed by reason of the vomiting; 16 oz., taken from a man servant, were then injected. He instantly revived and completely recovered in three months.

34. Reported in the *Gazette Medicale*, 1838, by M. de Berg; uterine hæmorrhage; aged 39. In this case secondary hæmorrhage occurred in four days after delivery; in consequence, transfusion practised. Recovered.

35. Reported in "Guy's Hospital Reports," Vol. II., p. 256, by Dr. Ashwell; uterine hæmorrhage. In this case the blood was first provided by Mr. Lever. 7 oz. being injected she revived, but sunk again, when more blood, taken from the husband, was transfused. She revived but sunk again, and died one hour after the operation.

36. Reported in the *Gazette Medicale*, Vol. VII., p 519, by Mr. Scott; hæmorrhage after the removal of a tumour; aged 14. This case occurred in the London Hospital. In consequence of collapse after the operation, transfusion was practised, but the patient died three hours after.

37. Reported in the *London Medical and Physical Journal*, by M. Blieding; violent hæmoptisis; aged 38. The patient was phthisical. The hæmorrhage could not be stopped till the next day, when it subsided under the use of external refrigerants and acid drink; five days afterwards collapse set in, when 6 oz. of blood from a man were transfused; a phlebitis followed from which he recovered in eight days. Got quite well in three months.

38. Reported in the *Medical Times*, Vol. XII., p. 214; *Northern Journal of Medicine*, Vol. III., 1845, by Mr. Brown, (Preston); prostration after instrumental labour; aged 37. This was a case of a woman liable to epilepsy. Labour occurring with great prostration, Mr. Naylor, the accoucheur, perforated and delivered the woman; collapse, however, came on; Mr. Brown called in. Ether and ammonia were given without effect; 4 oz. of blood, supplied by a female, were then transfused; re-action occurred before this quantity was transfused. Complete recovery followed.

39.—Reported in the *Archives Generales de Medicale*, Vol. XXIV., 1830, p. 132, by M. Goudins; uterine hæmorrhage. Mrs. G.; fifth pregnancy; hæmorrhage; intense collapse followed; 4 ounces obtained from a healthy woman transfused; recovery complete.

40.—"On Uterine Hæmorrhage," by Dr. Ingleby; prostration during gestation; hæmorrhage. The hæmorrhage having been frequent, much prostration following, transfusion was practised; as, however, opium was also given, the cure could not be certainly ascribed to transfusion.

41.—Reported in the *London Medical and Surgical Journal*, Vol. III., p. 588, by Mr. Banner; uterine hæmorrhage; aged 28; miscarriage; hæmorrhage persisted for 10 days; Messrs. Jeffreys and Bickersteth called in; 5 syringe-fulls of blood were transfused; this produced some feeling of oppression; she rallied, however, but sunk again in the course of 12 hours, but finally the rally was more permanent; and under the use of stimulants she completely recovered.

42.—Related by Mr. Walton; secondary hæmorrhage after the operation for phimosis. This case occurred in Bartholomew's Hospital; after the operation he was put to bed, but secondary hæmorrhage supervened: the collapse was so great it was supposed he would not recover; transfusion was then performed; the recovery was rapid and complete.

43.—Reported in the *Medico-Chirurgical Review*, Vol. IX., pp. 26, 613, by Mr. Brigham, (Manchester); uterine hæmorrhage; aged 19. Eighth child; placenta came away immediately, 3 hours after secondary hæmorrhage supervened; 4 hours after collapse complete; 2 oz. then transfused; no change; repeated twice again; then began to rally; 12 to 13 oz. altogether injected; rally and cure complete.

44.—Reported in the *Medico-Chirurgical Review*, p. 614, by Mr. Jewels; uterine hæmorrhage. This case occurred at the Middlesex Infirmary; Mr. Boyle operated; 4 oz. injected in jugular vein; death resulted; the *post-mortem* demonstrated the presence of air in the right cavity of heart.

45.—Reported in *Ryan's Medical Journal*, Vol. II., p. 29, by M. Dieffenbach (first case); Asiatic cholera; aged 27. Collapse complete; pulse quite imperceptible; the blood furnished by a young physician; aged 28; two deep inspirations followed; the eyelids opened and closed quickly; five minutes after, convulsions and groans; in another minute, death; autopsy demonstrated the usual appearances in cholera cases; the transfusion was practised through the right jugular.

46.—Reported in *Ryan's Medical Journal*, Vol. II., p. 29, by M. Dieffenbach (second case); Asiatic cholera; aged 65. Taken ill during night; first seen 8 a.m.; pulse imperceptible; vomiting and purging seldom; eyes sunken, cheeks sallow, tongue cold; no remedy had been used but the warm bath; transfusion practised; the blood was taken from a man, and injected in the left median vein. 1 oz. injected; no change; then 2 oz. more; the respiration became hurried: given mint tea, which she drank with avidity; the left jugular was then opened to allow a larger injection; 1 drachm of warm water was first injected, then 3 oz. of blood; no change was observed; the day passed off quietly; the pulse, however, did not return; she died six hours after the operation.

47.—Reported in *Ryan's Medical Journal*, Vol. II. p. 29, by M. Dieffenbach (third case), Asiatic cholera; aged 61; collapse of cholera well marked; the disease occurring during the night; in this case it was deemed necessary to ascertain if the circulation went on, and the brachial artery was exposed; it was found not pulsating and empty, and containing a coagulum like a thread; the transfusion was immediately performed in the brachial vein, which was found full of black blood; 2¼ oz. were thrown in at thrice; the man complained of no pain except when the artery was laid bare; after the third injection the pulse reappeared in the axillary artery, where it continued for five minutes, beating 60 in a minute; no blood escaped from the opened artery; the iris contracted several times, and the features appeared more animated afterwards; he died at noon, two hours after the operation, which did not appear to exercise any influence on the disease.

48.—Reported in the *Lancet* 1849, Vol. II., by Messrs. Walton and Routh; aged 34; Asiatic cholera; collapse being present, 30 oz. of blood were transfused, taken from a healthy male; he rallied for 36 hours, but sunk again 66 after the operation, from consecutive fever; the *post-mortem* demonstrated caries of the frontal portion of cranium, with an abscess between it and dura mater, and disease of the kidney.

From the above List we conclude—1st, That the operation is one of the safest major operations which may be practised in surgery.

The total number of cases here given are 48; the number of deaths, 18; giving a rate of mortality of 1 in 3—rather less than that of hernia, or about the same as the average of amputations, according to some authors.

A very little consideration, however, of the above Table will satisfy us that this average is too high. In all these 48 examples, it is true, the operation of transfusion was performed, but in some inadequately, and in others where there was no reasonable hope of deriving any benefit from it. In other of the cases, death was certainly due to other causes than the operation.

1°. In cases 5, 6, 12, and 16, the patients *were already dead* when the operation was performed.

2°. In case 8, as will be more especially noted in the sequel, enough blood was not transfused.

3°. In cases 7, 9, 15, 21, and 48, there was other mortal disease present; so that, although at first some benefit resulted from the operation this good effect was but transitory.

4°. In case 44 the operation was unfortunate, air having been inadvertently admitted in the veins.

And lastly, In cases 45, 46, and 67, the same objection applies as in case 8.

Thus, out of these 18 deaths we have only 4 in which death can be reasonably attributed to the transfusion, *i.e.*, out of 34 cases in all we have only 4 deaths, or 1 in 8½.

This result, however, is scarcely correct, though it accords with that obtained by Mr. Peet. This gentleman in a paper read before the University College Medical Society, now unfortunately lost, but an abstract of which appears in the *Lancet*, (1842,) came to the following conclusions. He collected 35 cases where transfusion had been performed. Of this number 13 died—an average mortality of 1 in 2·7. But he also remarked, that this result was incorrect, as among the fatal cases in 3 only could death be referred to a failure of transfusion, giving thus a total of 25 cases, of which 3 only were fatal, or 1 in 8·3.

I do not think, however, that the 4 first cases given in the Table should be included in this average. The accuracy of the record of these may and has been disputed; but, moreover, as the operation in these cases, excepting in the last, was not performed upon diseased persons, the facts only go to prove that transfusion, and that even with the blood of animals of a different species, may sometimes be practised upon comparatively healthy per-

sons with impunity. Excluding, therefore, these 4 cases, we have 30 cases, of which 2 only were fatal, or 1 in 10. This is a highly favourable result; more so, indeed, than that obtained in the other major operations, if we except that in lithotomy, obtained by Saucerot.

TABLE showing the AVERAGE RATE OF MORTALITY in MAJOR OPERATIONS, according to different Observers.

Operation.	Saucerot.		Dr. Inman.		Mr. B. Philips.		M. Roux.		M. Malgaigne.	
	No. of Cases.	Mortality.	No. of Cases.	Mortality.	No. of Cases.	Mortality.	No. of Cases.	Mortality.	No. of Cases.	Mortality.

2°. In reference to the diseases in which the operation has been performed.

a. In uterine hæmorrhage. The result is very flattering. It was performed in twenty-four such cases. In five the patient did not recover. In one only, however, could the operation be reasonably stated to have failed. In two cases (Nos. 5 and 12) death had already occurred. In one (8) sufficient blood could not be obtained. In another (44) air was accidentally admitted in the vein. In one only the benefit produced was transitory, and it failed (35.)

In four cases the hæmorrhage was secondary, coming on and continuing for some days after delivery. In all these it proved successful. (Cases 13, 34, 41, 43.)

In 2 cases the operation was performed before labour, and in both with a happy result.

b. After surgical operations, transfusion was performed 7 times (6, 20, 21, 28, 32, 36, 42), in 3 cases only proving fatal (6, 20, 21). In 2 of these fatal cases, however, (6 and 21), death is accounted for by other causes (6, 21). In both these cases the operation was performed for secondary hæmorrhage. The absence of a *post-mortem* in case 20, prevents the same conclusion in regard to the cause of death being stated with any degree of certainty.

c. It was twice performed in the state of exhaustion following continued dyspepsia. In one it was fatal, but the *post-mortem* here revealed organic disease, scirrhus of the pylorus. The other case was certainly cured by the operation.

d. It proved successful in one case, under the most unfavourable circumstances. In a case of phthisis, with violent hæmoptisis; and this is the more interesting, as the blood of a *ram* was the fluid used in this case. The quantity, however, transfused, was small, only 6 oz. It is, however, a fact of some interest; the more so, if taken in connexion with the cases 1, 2, and 4, where sheep's and calf's blood were employed; and must be looked upon as an instance of the power of the "*vis medicatrix naturæ*," where a patient got well in spite of the remedies employed, or as confirmatory of Dr. Harwood's experiments, and opposed to those of Drs. Blundell, Dieffenbach, &c.

e. It proved of no avail in one case of hydrophobia, and another of asphyxia.

f. It proved fatal in 3 out of 4 cases of Asiatic cholera. In the 4th it probably exerted a beneficial effect: probably that effect might have been permanent, but for the existence of other organic and mortal disease. In the other 3 cases, the quantity transfused was insufficient. In cholera especially, where the amount of fluid that runs away by the bowels is so great, we should expect *à priori*, that no advantage could be derived by the transfusion of a small quantity; the more so, as in those cases where injection of saline substances has been tried, as much as 100 oz. and 120 oz., and even upwards, have been transfused, with the best effect. This view of the case obtains apparently confirmation, from a simple review of the history of the four cases in which it was tried. Life was prolonged in proportion as the quantity injected was large. In case 45, 1½ oz. only were injected. He died in 6 minutes after the operation. In case 47, 2½ oz. were injected: the patient died 2 hours after the operation. In case 46, 6 oz. were injected: the patient died in 6 hours after the operation. In case 48, 30 oz. were injected, and death resulted in 66 hours. In the two last cases (46 and 48,) in the first, the cholera symptoms did not recur; in the last they were overcome. The injection of larger quantities in cholera derives further confirmation from the following calculations.

3°. As a rule, the quantity injected, where transfusion is practised, should not be under 7 oz.

It is admitted, that a lesser quantity may, and has been successfully transfused. Thus, in seven cases in the above Table, a cure followed under these circumstances:—

In case 22 there were transfused	2 oz.	Mean 3·8 oz. Say 4 oz.
" 23	2	
" 28	5	
" 37	6	
" 38	4	
" 39	4	
" 40	4	

But, on the other hand, where the quantity transfused before any symptoms of rallying took place, is distinctly stated in the above Table, we have the following result:—

In case 10 there were transfused	6 oz.	Mean 7·0 oz.
" 11	6	
" 13	6	
" 17	8	
" 19	5	
" 26	8	
" 28	5	
" 31	12	
" 40	4	

Thus it is, that we explain the failure of the operation in cases 8, 45, 46, and 47, a sufficient quantity not having been transfused. This result is still more certainly brought out by the following Table, where the fatal and successful cases, and the quantities transfused, are opposed for the purpose of making this more evident, arranged in separate columns, beginning with the smallest mean quantity transfused in successful cases, one column being set apart for every additional 4 oz. up to 16. In this table, the 4 first cases, and the 4 cases in which death had already occurred, when the operation was performed, are excluded:—

Under 4 oz.				4 and under 8 oz.				8 oz. and under 12.				12 oz. and under 16.				16 and above.			
Fatal.		Cured.		Fatal.		Cured.		Fatal.		Cured.		Fatal.		Cured.		Fatal.		Cured.	
Case.	Oz.	Case.	Oz.	Case.	Oz.	Case.	Oz.	Case.	Oz.	Case.	Oz.	Case	Oz	Case.	Oz.	Case.	Oz.	Case.	Oz.
8	3½	22	2	7	6	24	4	21	9	11	9	9	12½	10	14	...	...	13	16
45	1½	23	2	44	4	28	5	36	10	14	8	...	...	18	15	20	18	33	16
47	2½	...	...	46	6	30	5	...	...	17	8	...	...	19	12	48	30	31	24
...	...	...	...	...	...	37	6	...	...	27	11	...	...	41	14	...	...	26	21½
...	...	...	...	...	...	38	4	...	...	32	11	...	...	43	12½	...	...	...	...
...	...	...	...	...	...	39	4	...	...	...	...	...	...	...	...	...	...	...	...
...	...	...	...	...	...	40	4	...	...	...	...	...	...	...	...	...	...	...	...
3	2·5	2	2	3	5·3	7	4·5	2	9·5	5	9·4	1	12½	5	13·5	2	24	4	20·1
1 death to 0·7 cured.				1 death to 2·3 cured.				1 death to 2·5 cured.				1 death to 5 cured.				1 death to 2 cured.			

from which it appears, that the greatest proportional number of successful cases are those in which a quantity not less than 12 oz., or more than 16 oz., was transfused; the number of successful cases proportionally increasing up to this limit, and then diminishing again, giving a mean of 14 oz., as the quantity to be transfused.

The same result is brought out, though more generally, if we arrange these series of cases in two classes only; the one, where the quantity transfused was under 12 oz., and the other where it exceeded this number:—*i.e.*, we have in the former class 8 deaths, with an average of 5·3 oz. transfused, and 14 recoveries, with an average of 5·9 transfused, or 1 death to 1·7 (or nearly 2) recoveries, and in the latter class we have 3 deaths, with an average quantity 20·1 oz. transfused, and 9 recoveries, with an average 16·5 oz. transfused, or 1 death to 3·2 recoveries.

From which we think it follows, that, as a rule, the quantity transfused should not be less than 6 oz., nor more than 16 oz.

4°. In regard to the age of the patients in which this operation was performed, the data are insufficient in the fatal cases. In the 16 successful cases in which the age is given, the mean age was 34·8. In 3 cases the age was under 30; in 4, under 35; in 5, under 40; and in 3, under 42.

5°. The danger of the operation is certainly not great. Among the successful cases, phlebitis, which *à priori*, we should most fear, occurred in only one case, case 37, where the blood was taken from a *ram*; but even in this case it was easily overcome. In the only 3 cases where we have seen, after transfusion, death followed (cases 20, 35, and 36), the operation could only be said to have failed to cure, but not caused death; and even in one of these, (case 20,) Dr. Blundell expressed an opinion that there was some other latent cause of death.

6°. In regard to those diseases in which this operation might be performed, I think there are many in which, by reason of a mistaken timidity on the part of the practitioner, it has not been practised; and where the probability is, that if the contrary course had been pursued, life might have been spared. Too much hardihood is certainly very blameable, but timidity is scarcely less so. The misfortune is, however, that death might be frequently improperly ascribed to the operation, if it failed, and more especially, as it might be improperly performed. With the state of public feeling, therefore, it can at present only be resorted to in extreme cases. We can, therefore, only speak of it as applicable in those diseases where collapse is present or imminent.

From the Table we learn that out of the 18 cases in which it failed or proved fatal, (in 5,) other organic disease was present. In only 2 cases where there was or had been organic disease, did it prove successful. While, therefore, these figures do not absolutely forbid the employment of transfusion in organic disease, they very much discourage it. Common sense would necessarily contra-indicate its practice, especially in diseases of the lungs or heart.

But, first, in all cases of collapse induced by hæmorrhage, whether primary or secondary, it should always be employed.

Secondly, in that state of extreme exhaustion from dyspepsia, where collapse is imminent, it might be advantageously employed. There are many cases in which dyspepsia has persisted for a long time, and perhaps been neglected, and where, notwithstanding, no organic disease can be detected; in which no food can be retained on the stomach, and the remedies employed are powerless. Here the patient will sink from inanition, if something is not done. In these cases it is highly probable, that were the operation more frequently resorted to, life might often be saved. Dr. Blundell kept a dog alive three weeks, by consecutively transfusing the blood of another dog in his veins. It is true, in this case the animal lost weight, and was evidently thinner at the end of the time; but the operation, once performed in a full and effective way, might enable the patient to rally, so that other remedies might subsequently have effect.

Thirdly. In some cases of stricture of the œso-

phagus, where no food can be taken, to give the patient time to rally, so as to admit the introduction of bougies subsequently.

Fourthly. In the collapse which follows long-continued fevers, more especially those of a typhoid character, produced frequently by supervening diarrhœa, or by the crisis of the disorder. It is exceedingly probable, transfusion here might be most advantageous. In that variety of Irish fever, so fearfully fatal, and where the crisis is marked by excessive perspiration, in the exhaustion that invariably follows, and from which the patient so seldom recovers, it might be successful, giving the patient time to rally; for then the digestive organs are too often too slow and too weak in their operation to act with effect, whereas a sudden change in the quality and richness of the blood would probably save the patient. But even after the crisis, in a more advanced stage of the convalescence, death not unfrequently results, after a continued fever, from progressive weakness, and here transfusion might probably effect a cure.

Fifthly. In the collapse, or great exhaustion, following diarrhœa, dysentery, and cholera, where the use of injections especially would be contra indicated, or useless, it might be, probably, advantageously employed. Among children especially, diarrhœa is a very common cause of death, from the mere exhaustion which it produces, although, it is true, in some of these cases, there may be organic disease, which would neutralize the good effect of transfusion; but even in these cases, sometimes, it might do good, by giving time for subsequent and successful treatment.

The same remarks apply to the exhaustion after sporadic cholera. In many of these cases, fatal syncope is at once induced by the patient raising himself in bed, even after all the active symptoms of the disease have subsided, denoting great weakness, which might be effectually combatted by transfusion.

Lastly. In Asiatic cholera. In the state of collapse, whether by reason of the nervous shock induced or not, we can trace two, at least, efficient causes. 1. Diminished fluidity of the blood, produced by the violent watery purging; but, 2. it would seem, from the non-secretion of urine and bile, that some essential vital principle in the blood (necessary for the stimulation of that part of the nervous centres connected with these organs, or the particular nerves of the organs, or with their secreting cells themselves) is either so removed, or so changed in kind, as no longer to produce this stimulating effect. That it is not always so removed, is proved by the fact, that the transfusion of saline substances has sometimes cured the disease; but that it is frequently so, is also proved by the frequent failures of this mode of treatment. If his view be correct, to restore this principle becomes the first indication in the treatment. We do not know what it is. But the transfusion of blood, which, as blood, does contain this principle, would seem the best calculated to fulfil this indication.

In the four cases of cholera above given in the Table, we have some confirmation of this view. In Cases 45 and 47, the quantity transfused was too small to produce any change. In Case 47, where six ounces were transfused, life was prolonged six hours; and in Case 48, where thirty ounces were transfused, the choleraic symptoms disappeared, bile being secreted, and life prolonged sixty-six hours. It is impossible to ascribe, upon the evidence of one case, these amendments to the transfusion. More experiments are required, but the coincidence is interesting.

The objections of transfusion in Asiatic cholera seem to be twofold. 1°. The difficulty of obtain ing a sufficient quantity of blood. In the cases treated and cured by transfusion of saline substances, as much as 100 to 320 oz., and upwards, were sometimes injected. To inject this quantity of blood would be impossible, but it is probable a smaller quantity of blood would suffice; and if not, the transfusion of blood might be combined with the transfusion of saline substances, the one operation preceding the other.

2°. The second objection is the fear of contagion; but, even here, kind friends will be frequently found willing, at any risk, to save the life of a relative; and here we must depend upon the feelings and affections of others. How far these theoretical suggestions are correct or false, can only be proved by further experiments. The dreadful havoc now produced by the cholera on all sides must be the excuse for their promulgation.

Sixthly. It remains only now to add a few words on the method of performing the operation itself, and I cannot better do so than in quoting the very words of my friend and colleague Mr. Walton, who has kindly furnished me with the following remarks on the subject:—

"The operation may be executed in three ways —1. By receiving the blood in a vessel, and allowing it to enter the body by gravitation. 2. By interposing a tube between the blood-vessels of the emittent and recipient persons, and trusting to the force of the circulation for its transmission. Both these methods have given place to the 3rd or injecting process, which is effected by the stop cock stomach pump; but, instead of the tube through which the pump would be filled, there is a funnel-shaped basin to receive the blood. Much nicety is required in its make.

"So little is the theory of transfusion understood by instrument-makers in general, that instruments are made and sold for the purpose that are wholly inapplicable. Mr. Coxeter furnished me with mine. Mr. Fergusson, of Smithfield, has produced the most perfect one that I have seen. The basin should be cased like a hot plate, that it might contain water. The piston should fit accurately, and at the same time work freely. I think that an interruption, by some elastic material in the tube that is to convey the blood, is advisable, for then the pipe that is inserted into the vein is less likely to be disturbed by any motions which may arise in the working of the syringe or movements of the patient. At least three persons are required for the safe and efficient performance of the operation, and their attention should be wholly given to it. Supposing everything ready, the instrument quite clean, air-tight, and thoroughly warmed, the basin filled with hot water, a vein in the patients arm should be punctured, and the finger applied to the orifice till the tube is ready to be inserted. It is quite unnecessary to dissect out a vein, and place a probe under it before making the puncture, as has been recommended. A vein in the arm, from which the blood is to be taken, is next to be opened by a fine cut, and the stream directed into the centre of the basin, the arm being held close to it. When sufficient has entered, the syringe should be filled, and the piston pushed in a little till blood flows at the end of the pipe, which is then to be introduced into the vein. The injector now works the syringe till the desired quantity has been thrown in. There should be no cessation to the stream of blood entering the basin till the operation is ended, so that, after each occasion of the syringe being filled, there may be at least an ounce of blood at the bottom of the basin, or else air would probably be sucked in. It will be perceived that I have given merely a hasty sketch, but sufficient, I think, to guide those who have no experience in the operation. The accident to guard against is the transmission of air. The greater facility with which this is likely to occur when transfusion is performed through the jugular vein, points out the impropriety of selecting this vein for the operation. It would be worse than useless to attempt to transfuse unless an expert bleeder be procured. Much of the success of the operation depends on the despatch, as well as the steady and uninterrupted course that is pursued; for, with the disadvantage of the blood travelling over dead surfaces, very little exposure of it to air must be apt to destroy vitality.

"The above account has been given, as the subject of transfusion is usually excluded, in works even of Practical Surgery, although much simpler operations are treated in detail. Even Cooper's Dictionary 'is silent on the subject.'

Dorset-square, July 26, 1849.

MEDICAL SCHOOLS AND UNIVERSITY TOWNS OF GERMANY.

By Dr. BUSHNAN.

(Continued from page 72.)

STATE OF MEDICINE IN BAVARIA.

After the full detail given of the medical organization of Prussia, it will be unnecessary to enter at any great length on the state of the profession in Bavaria. Recently many and most important modifications have been introduced. The changes thus introduced have affected materially both the system of study, and the social position of the profession at large. The most recent enactment thereon bears the date of the 19th October, 1843. Pursuing the same plan as in the History of Medicine in Prussia, we commence with the Medical Hierarchy, which is almost exactly on the same footing as in Prussia. The Central Board is attached to the Ministry of the Interior, and consists of a President and four members. It constitutes a court of appeal in cases of medical police, and is charged with the superintendence of a sanitary police and public hygiene. It exercises also a complete control over the appointments of the President and Vice-Presidents of the Courts of Examiners. It discharges its duties only through the responsibility of the Minister; all its decisions passing under the seal of the Minister of the Interior. The correspondence it carries on with inferior medical authorities can only be effected through the medium of the Minister of the Interior.

The District or Provincial Committee, under the direction of the local authorities, is composed of a President, four practising doctors, a chemist, and a veterinary surgeon; it is charged with the general and special management of the sanitary police and public hygiene of the district, and the investigation of the private and professional life of the medical practitioner! This is done annually, and the report forwarded to the chief of the district, by whom it is transmitted to the Minister of the Interior. The tenor of this scrutiny into private life may be best judged from the following heads of the queries constituting the basis of the report:—Name, residence, date and locality of birth; married or single; number of children; religion; notes of university examination; income; character and disposition; knowledge and practical ability; activity; attachment to the Monarch and his august family, and to the actual Government; moral conduct; demeanour towards patients; services rendered to the State; private remarks.

Subordinate to these, and forming the first step in the scale of the Medical Hierarchy, are the Inspectors of Cantons; they receive the name of doctors of the judicial circles. They are entrusted with the enforcement of all the regulations and orders relating to the practice of medicine, pharmacy, and sanitary police; they superintend vaccination, and assist in the tribunals of the Courts of Justice.

MEDICAL STUDIES.

These are pursued at any of the three Universities of Munich, Würzbourg, and Erlangen, and extend to a period of seven years.

The first two years of study are occupied in Chemistry, Botany, Mineralogy, Zoology, and Natural Philosophy.

The three succeeding years are spent in the acquirement of strictly Professional knowledge under the Faculty of Medicine.

The last two years are specially devoted to the practical departments of the Profession in the Hospitals.

On the conclusion of each of those respective periods, the student is subjected to an examination on the topics which have been embraced in the course.

These examinations take place before a Senate nominated for the purpose in each of the Bavarian Universities. The first is called the admission examination, and comprises the studies prosecuted during the first two years; and should the student not be found competent, he is remitted to his studies for six months.

The second examination, denominated the theoretical examination, takes place at the termination of the fifth year of study. In it are embraced all the subjects which properly constitute the theory of medical science. Each candidate is examined for two hours, and, in case he is not found competent, he is required to study an additional year. In certain cases this period may be restricted to six months.

The final examination is chiefly on practical subjects. It is continued for eight days; is partly *viva voce*, partly in writing; and averages about eight hours daily. The questions are all determined by lot, and the answers prepared under the incessant observation of one of the examiners.

When the candidate has satisfied the Commission of Examiners on these different subjects, he is then at liberty to present himself for the degree of doctor. To obtain this the student has to submit a thesis, and to defend it publicly, having among his opponents a professor belonging to the faculty, a doctor, and a candidate. The discussion continues for two hours. On the promotion to the degree of doctor, the senatus academicus and all the professors of the faculty of medicine are present. The President pronounces a brief eulogy on the candidate, who on being declared a licentiate in medicine, repeats the oath of Hippocrates.

AUTHORITY TO PRACTICE MEDICINE.

But the candidate, who has now acquired the degree of Doctor, is not forthwith at liberty to commence practice. In accordance with a regulation passed in 1835, the Government of Bavaria has restricted the number of practitioners in each district. In virtue of this decree, an exact list is to be preserved of all licensed Doctors, and on the decease of any of them, intimation is given to the Government, by whom the situation is filled up. Should there be an excess in the number of expectants, the young aspirant has no alternative but to wait till another death occur, unless he has sufficient influence and character to induce the Government, to create a new appointment for him. When the authority to practise has been once acquired, and the Doctor regularly located, he has full power to officiate in any of the three branches of Medicine, Surgery, or Midwifery.

By a decree passed in 1843, a subordinate class of practitioners, called Bathers, were partially suppressed, and the practice of Medicine, Surgery, and Midwifery, placed solely in the hands of the Physicians who have passed the University Curriculum. This class are still retained, with authority to bleed, to apply leeches, sinapisms, and moxas; to practise as dentists; and to take charge of the sick. They are also allowed to give relief in cases of apoplexy and asphyxia, and to sell diachylon, sugar of lead, ammonia, and nitrate of silver. With this privilege, limited as it is, they nevertheless contrive to make no inconsiderable inroads upon the practice of the regular Physicians.

THE MILITARY MEDICAL CONSTITUTION OF BAVARIA.

The class of Doctors supply the medical men for the army. They officiate, first, as assistants in the Military Hospital of Munich, at a salary of about 40*l.*; and then progressively advance, to the post of Medicine in Chief of the Staff. There is, however, not so much consideration paid to the military surgeons in the secondary Germanic States, as in those kingdoms which possess a large standing army.

MEDICAL ORGANIZATION IN THE KINGDOM OF WURTEMBURG.

In this State, the hierarchy of the medical functionaries is the same as in Prussia.

The Faculty of Medicine of the University of Tubingen confers the honorary degree of Doctor, after a three or four years' course of study. To procure the license to practise, it is requisite to undergo two State-examinations. The candidate has to declare whether he intends to practise Medicine, or Surgery, or both, the examination being modified accordingly. The first examination takes place twice annually at Tubingen, before a Committee formed of the Professors of the Faculty of Medicine there, with a member of the Superior Medical Board of Stuttgard. Prior to admission to this first examination, the candidate must give adequate proof that he is 21 years of age; that he has attended the University Lectures for three or four years,—the Doctor's degree is not essential;—that he has attended, for the period of one year at least, the National University of Tubingen; and that, further, he has not been a member of any University Secret Society.

The second examination takes place at Stuttgard, and bears chiefly on subjects of a practical nature. An interval of a year elapses between the two, during which hospital practice is generally followed.

When the candidates have passed these two examinations, and taken the oath of allegiance, they are permitted to reside and practise their profession wherever they judge proper.

There are also second and third class surgeons in Wurtemberg, whose education is not so extensive as that of the first class medical men. Those of the second class are not permitted to perform any difficult or dangerous operation, and they cannot prescribe without the advice and direction of a physician. The surgeons of the third class undergo a very slight examination, and they are only required to be acquainted with what is called minor surgery. As in all similar circumstances, these persons affect considerably the practice of the more regular Medical men, and thereby are a source of no small degree of bad feeling amongst the members of the Profession.

MEDICAL ORGANIZATION IN THE GRAND DUCHY OF BADEN.

The position of the Profession in this Duchy is almost the same as in the Kingdom of Wurtemberg. The diploma of doctor of medicine is not essential as a preliminary condition to the acquirement of the licence to practise medicine. For this the State examination, conducted by the Committee of Health, is sufficient. The candidate has to appear twice before the examiners; and he is examined on medicine, surgery, or midwifery, —for each of which there is a separate section of examiners—according as he proposes to practise one, or other, or all these branches of the healing art.

The inferior grade of practitioners are not compelled to go through any university course, their knowledge being usually acquired by assisting the higher practitioners. They submit to an examination before the inspector of the locality in which they dwell, and they generally keep barber's shops.

The Grand Duchy of Baden has two universities—the Catholic Fribourg, and the Protestant Heidelberg. The Faculty of Medicine at Heidelberg enjoys, with good reason, a very high name. The course of practical instruction there is very superior. Chelius is professor of surgery; Gmelin professor of medical chemistry; and Tiedemann of physiology.

MEDICAL ORGANIZATION IN THE KINGDOM OF SAXONY.

There are two medical schools in Saxony, the Faculty of Leipzig, and the Medico-Chirurgical Academy of Dresden. In the former the course of instruction is complete; while the latter is chiefly devoted to practical medicine and surgery. In the Faculty of Leipzig the title of doctor is obtained after the University course of study. With this title the doctor acquires the right to practise throughout the whole Kingdom. There is no State examination in Saxony. There is, however, a very strict law in force as regards the distinction between surgeons and physicians, properly so termed. In virtue of it, passed in 1824, a fine of money, or imprisonment, or even temporary suspension from the exercise of his profession, attaches to any surgeon who practises in cases of internal disease.

The medical men educated at the Medico-Chirurgical Academy of Dresden, do not receive the titles of Doctors, and are only at liberty to practise in those localities where there is no regular physician. By a Royal decree of 1824, these practitioners of the second order cannot exercise their profession unless under the control of an inspector, to whom they are obliged to transmit quarterly, tables of their cases, the results, and such remarks as they think necessary to record.

The duration of study at the Medico-Chirurgical Academy is three years for surgeons, and four years for physicians. They are altogether of a practical character, and seem originally to have been intended for students of limited means.

MEDICAL ORGANIZATION OF THE KINGDOM OF HANOVER.

The Committee for the State examination, which has its seat in Hanover, grants the authority to practise. There are the two distinct branches of medicine and surgery; and of the latter there are two classes—a division or distinction which does not meet with general support.

No physician is permitted to establish himself without having previously intimated his purpose to the local authorities, and received permission to do so. Moreover, the number is restricted in all towns with a population of less than 4000.

In Electoral Hesse, and in the Grand Duchy of Hesse Darmstadt, there is little difference in the medical organization from that enforced in Hanover. The same may be said of the Duchies of Weimar, Saxe Coburg, Saxe Meiningen, and Saxe Altenbourg. As these States are small, they contribute to the support of the University of Jena. They are all necessarily deficient in the routine of hospital instruction.

PROGRESS OF MEDICAL SCIENCE.

GERMANY.

THE TOTAL ABSTINENCE QUESTION, AS VIEWED IN GERMANY.

The subject which has received in this country the ludicrous title of the "teetotal question," has excited more or less attention elsewhere; in proportion, on the one hand, to the reflective character of the nation, and, on the other, to the prevalence of those habits against which the movement is chiefly directed. Recently a short paper appeared in a German Journal, the *Vereinte Deutsche Zeitschrift fur die Staats-Arznikundi*; which contains most of the essentials of the question, stated in a very terse, common sense way, and by an unprejudiced observer.

Dr. Metz, some time ago, started the project of a national expression of opinion, by the German Medical Profession, upon the use of brandy,—in which question brandy represents alcoholic fluids generally, —and, from what can be gathered in the Paper before us, the opinion which he proposed for adoption would seem to have been strongly condemnatory and prohibitive.

Dr. Stromberg delivered a discourse on this project before the Union of Hessian Physicians in Darmstadt, which was reported in the Journal above named.

The evil effects of the habit of excessive brandy drinking the Author fully admits; and he notices, with much gratification, the existence of societies, whose object it is to abolish this practice. He states, that no doubt it is the duty of every Medical man, in his own sphere, to encourage, so far as in him lies, this important object of Medical police. But, when the Profession, as a body, are required to give their united Medical testimony, he regards it as absolutely necessary to their evidence making the desired impression, that it should be founded on *facts which are incontrovertible, in every way unexceptionable, and applicable to all circumstances.* When these facts are *not* susceptible of such universal application, they must be proportionally modified.

This fully applies to the statement of the project. The use of brandy, by which we understand, that of all distilled drinks, is *in no way* necessary to the health of man or the upholding of life; but, *on the contrary, hurtful.*"

Now, if this assertion were true unconditionally, and under all circumstances, then we could no longer concur with the wish expressed in a

quent part of the project, that the use of this drink should be placed under wholesome limits. It would rather be the duty of a good Medical police, to close all distilleries, and rigidly prohibit the sale of brandy, as being a *poison*. This statement, however, when made without any limit, without any reference to a moderate use, to individual constitution, to particular localities, cannot at all be sanctioned.

Our peasants, who sustain violent labour on unstimulating food, make use of brandy in the absence of any other exhilarating fluid as a customary drink, as a *dietetic;* and, as daily experience shows, without the least prejudice to their health. Still we will not say, that in the majority of them it is indispensably necessary. Just as little does its moderate use injure soldiers engaged in the fatigues of their profession;—on the contrary, it is useful.

The projected Report also states, "that the often-repeated, and even moderate use of brandy, induces dangerous diseases, and makes recovery from others difficult." Against this the Author adduces the custom of Northern Germany, where liqueurs are introduced into the drawing-room after a meal without either disease or death following them.

Again "total abstinence from brandy contributes greatly to health and prolongation of life."

Now, though certainly there are always possibilities of brandy doing harm, *i.e.*, of its being in some circumstances detrimental to the organism yet this is greatly compensated by the effect of habit —an effect which is seen in the similar manner in which the organism becomes accustomed to other stimulants—coffee, tobacco, opium, &c. As there is no precise state of normal health, so neither is there a perfectly normal diet; and so long as there are a large mass of the poor who are equally devoid of good food, warm clothing, and a warm residence in winter, and so long as brandy forms a kind of succedaneum for these, we have no right to maintain that it should be prohibited.

The Author quotes an English (Edwin Morris) and a German (Wallack) Practitioner who both agree in the greater liability of teetotallers to be affected by the ague poison.

He also quotes another authority, who corroborates his statements concerning the harmlessness of brandy, as drunk by peasants and soldiers. The same authority adds, that the ill effect solely arises from the disproportionate use of brandy, while the proposition that excess is prejudicial, is not limited to brandy, but applies to all food and drink.

Hence, the Author concludes, that the judgment expressed in the project is too roughly and too generally expressed, and is only applicable to a disproportionate use of brandy, relatively to the habitual drink.

He judiciously adds, that the proposition, as thus corrected, is no new statement, even to the laity, and needs no confirmation, or subscription to, by the German Medical Profession. While, on the other hand, the exaggerated and overstretched meaning originally comprehended by the projected Report, would only excite doubts of the real facts, and, by hindering the spread of the temperance cause, would do more harm than good.

He thinks the consultation and discussion of the Profession upon this point of great importance, but doubts the propriety of a local assemblage and decision, or of the result being promulgated in the teeth of a minority, as the *united voice* of the Profession. More real advantages, he thinks, would be derived from numerous separate communications from different practitioners, each contributing the results of his own experience, and thus affording materials for a contrast of the most widely separated districts, and the most various circumstances.

SCOTLAND.

[From our Edinburgh Correspondent.]

We were all here much gratified with the Biographical Memoir, in last Saturday's *Medical Times*, of Dr. John Reid, of St. Andrew's, which, as the first Professional notice of one so well known in Edinburgh, has caused a sensation commensurate with the esteem in which he was universally held. With one voice, we subscribe to the sentiments expressed in the Article. Some ten or twelve of our medical brethren of Edinburgh went on Friday to St. Andrew's to attend his funeral, among whom were three Edinburgh Professors, Dr. Alison, Dr. Simpson, and Dr. Bennett. He was interred in the burying-ground, amidst the ruins of the Cathedral of St. Andrews, at the foot of St. Rule's, one of those ancient structures, towering to upwards of hundred feet, whose origin is lost in the mists of antiquity. High as it is, the little balcony at the top was crowded with as many spectators of both sexes as it could contain. The funeral was attended by the Professors in their robes, headed by their distinguished Principal, Sir David Brewster, by as many students in their gowns as remained at this season in St. Andrews, and by the chief inhabitants of the place, as well as many private friends from a distance. The result of a *post-mortem* examination of the seat of the disease, by which he was so prematurely cut off, will doubtless be made known to the Profession ere long.

Dr. Reid's death raises a question which agitated the University on the demise of the former incumbent, Dr. Briggs. The appointment held by the latter was, the Professorship of Medicine, with the understanding, that he was to teach Anatomy, if a certain number of students offered. It appears that, during the whole of his incumbency, only one student offered for anatomy. Dr. Briggs, accordingly, taught nothing but chemistry down to the time of his death. About that time an endowment, made some time before, to establish a Lectureship on Chemistry became available, and Mr. Conel was appointed. A proposal consequently arose, to convert the Chair of Medicine, held by Dr. Briggs into a Professorship of Natural History, which however, was negatived, and Dr. Reid was appointed Professor of Medicine and Anatomy. And this proposal, it appears, will be revived on the present occasion. The patronage of the Chair lies with the Professors, though it is far from certain that they have the power to change it from a Chair of Medicine, as fixed by Act of Parliament, to a Chair of Natural History. The history of the Chair is easily given. The Duke of Chandos, when Chancellor of the University, in the early part of the last century, gave a sum to institute a Professorship of Oratory; but the Professors of that day, thinking such a Chair unnecessary, petitioned him to apply his gift to found a Professorship of Anatomy. It appears, however, that anatomy was never taught till Dr. Reid's appointment, and even then, not by means of recent subjects, but only so long as the wet parts, which he had stored up at Edinburgh, remained unexhausted. It seems to have been hitherto next to impossible to procure a supply of subjects at St. Andrews. The impossibility now lies in the Anatomy Act; for, under the old practice of body-snatching, it must have been as easy there as elsewhere. Be that as it may. In the middle of the last century, when the two old Colleges were made, by an Act of Parliament, the United Colleges, the Chandos foundation is everywhere described in that Act, not as the Professorship of Anatomy, but as the Professorship of Medicine; or, as Sir David Brewster says, in his evidence before the Medical Reform Committee, there is not a Professorship of Anatomy in the University, but only a Professorship of Medicine. If this Chair be converted into a Chair of Natural History, St. Andrews must give up the practice of granting degrees in Medicine.

Of late, the St. Andrews degree has undoubtedly gained considerable in the esteem of the public. Dr. Reid's character was, in particular, felt to be guarantee that it would not be conferred on the unworthy. It is now a highly respectable degree, though it would be absurd, as a Correspondent of the *Medical Times* did lately, to set it above the Edinburgh degree. The old method of granting it, on the certificate of two known Medical men, was decidedly objectionable, notwithstanding that the declaration of fitness was made on soul and conscience, and that the names of such men as Boerhaave, Baillie, and Abercrombie, are to be found in the list of attesters. Now, the degree is hardly ever conferred on any who do not already hold the diploma of surgeon. It is given only after an examination in regular form by each of five Examiners, in the presence of as many members of the University as choose to attend; and not unfrequently men already possessed of the diploma of the London or Edinburgh College of Surgeons are refused. It is undeniable that St. Andrews desires a continuance of the power to grant degrees for the sake of the profits; but these profits do not go to the examiners, but to the support of the library, the fee of the Examiners being paid by the candidate, whether he passes or not. If the proposed Medical Reform Bill is ever to pass, it does not very clearly appear what is to become of the St. Andrews degree. In its extra-mural Examiners it already possesses a part of the machinery by which that measure proposes degrees to be conferred. But St. Andrews never can become a medical school any more than Oxford or Cambridge. If a larger preliminary education be hereafter made requisite for the medical degree, St. Andrews will afford an excellent and cheap school for that purpose. So far from presenting any appearance of decay, the city itself, small though it be, shows just now the unmistakeable look of a thriving and prosperous place.

The Edinburgh summer session is just over, and some new arrangements begin to be talked of for the approaching winter. The extra-academical medical lecturers are to occupy jointly a newly fitted-up building behind the College of Surgeons, with an entrance from Nicolson-street. The only change in the lecturers spoken of is, that Dr. Richard Mackenzie, a promising young surgeon, is to join Dr. J. A. Robertson in the course of Surgery. Some improvements in the University clinical courses are contemplated.

A recent rupture between the Managers and Resident Medical Officers, or house clerks, of our Infirmary transpired a week or two ago. It had nothing to do with the professional duties of the House, the clerks being at the time, as regards their proper business, very efficient and exemplary in their conduct. The *fracas* commenced between the Matron and the clerks, touching that most important part of the business of life which is transacted daily at the dinner table. The clerks, who are required to board in the establishment, found fault with the meagreness of their fare, and entertained the Matron so freely with their complaints that she at last declined to appear at table. The quarrel still kept smouldering on, fanned by occasional petty annoyances on either side, till, at last, it burst forth in a simultaneous appeal by both parties to the House-Committee. An inquiry is set on foot, and, as might have been anticipated, the Committee is bewildered with the contradictions of the evidence. By-and-bye the Board of Managers come to the rescue, with no better success as regards a clear perception of the real origin of the broil. Then follows the usual allowance of admonitions, denials, counter-statements, and all the confusion worse confounded, that, by the very constitution of human nature, flows forth under such psychological circumstances. The moral of the whole is, that it is idle in the extreme to think of making a clear case out of such elements. The proper course was one which he who runs may read. The past should have been held to clear scores on both sides—"post malam segetem serendum est," so some ancient says. If both parties had been simply exhorted to begin a new leaf, much profitless irritation might have been spared, and the Managers would have sooner obtained the blessing due to peace-makers. The Matron deserves commendation for the spirit in which she seemed resolved to do her part thereafter. She began with advertising for a cook in the newspapers. We trust she has fallen in with a good one; for what avails the raw material of a bill of fare, before the effect of the cook's workmanship appears? Young Medical men living in a hospital can rarely bolt their meals like a ploughboy or a sportsman. Confinement, their occupations, and the air of the place, soon sink the appetite below the level of keen. There all the difference in the world between

pampering the appetite and enticing it, when it flags, by somewhat delicate and well-dressed food; and hospital clerks, especially when there are hard students among them, can hardly thrive but on this kind of fare. The governors of hospitals are very apt to complain that Medical men, and especially young Medical men, are difficult to deal with. It is probably true. But, then, the reason why the governors get into difficulties so often, is, that they take up the wrong idea, on each new occasion of strife, that they are dealing with wayward individuals; whereas, they are dealing with a class, and a class cannot be dealt with judiciously unless pains have been taken to understand their peculiar wants and class-feelings. But it is the business of the governors to study the feelings, prepossessions, and even prejudices, of a class which they can no more dispense with than they can with patients. Until a governor has made some progress in this study, he is but a journeyman in his craft; and if there were more masters in the craft of hospital governor, there would be but few dissensions.

ENGLAND.

ON THE PURGATIVE PROPERTIES OF OIL OF ANDA.

By ALEXANDER URE, Esq., Fellow of the Royal College of Surgeons of England, and Surgeon to the Westminster General Dispensary.

[From the "Pharmaceutical Journal."]

I was requested, some months back, by your Professor of Pharmacy and Chemistry, Mr. Redwood, to investigate the therapeutic properties of an oil expressed from seeds imported from the Brazils, and which seeds are much used by the natives of that country as a cathartic, in doses of from one to three. The plant which yield it is the *Anda Gomesii*, so named after Gomes, who described it, although a previous description had been given by Piso. It belongs to the natural order of Euphorbiaceæ, and to that of Monœcia Monadelphia in the sexual system. In referring to the *American Cyclopædia of Practical Medicine and Surgery* (Vol. I., Philadelphia, 1834) we learn that "the part used in medicine is the fruit, which is about the size of an apple, and of an ash-colour. On removing the external husk a nut is presented to view, which is about two inches in diameter. It has a hard shell, which, on being broken, exhibits two cells, each containing one seed about the size of a chestnut." . . . "By expression these seeds furnish a clear, pale, yellowish oil, which is destitute of taste and almost of smell; at common temperatures as fluid as olive oil." From experiments made in the Pennsylvania Hospital, by Dr. Norris, it appears that in doses of fifty drops it generally induced one evacuation, and in larger quantities operated copiously.

The oil employed by me, kindly supplied by Mr. Ince, of the house of Godfrey and Cooke, had a specific gravity of ·927, and corresponded in sensible properties to the above description. I found, however, a smaller dose suffice to produce a purgative effect than that stated on the authority of Dr. Norris. I believe, indeed, that many purgative remedies in small doses increase the peristaltic motion, and thus insure evacuation, which in larger doses would occasion only colic pains and costiveness. This fact is based on the physiological principle, that slight stimulants are more efficient than those of a violent character in awakening sympathetic action.

I now adduce short abstracts of some cases in which this oil was tried:—

D. H., aged 20 years, came under my care for scrofulous disease of the hand. Had been troubled with constipation of the bowels since infancy; having an alvine discharge, upon an average, once in three days; the evacuations being hard and scybalous. He was directed to take, upon the 11th of October, 1848, twenty drops of the oil of anda every morning on a lump of sugar. On the 18th he informed me that the first dose operated freely as an aperient, the second dose on the following day and the third dose also, but seemed to occasion some nausea. This man was of a marked scrofulous habit, and most probably owed the nausea to some coincident irritability of stomach.

A. H., aged nineteen years, of spare make and sedentary habits, was admitted under me on the 27th of November, 1848, for an eruption on the skin. She complained of headache, uneasiness of the chest; her bowels were so constipated as to be partially unloaded but once in three days; her tongue was white, and she felt feverish. She was ordered saline effervescent draughts and twenty drops of oil of Anda every morning on a piece of sugar. On the 11th of December it was reported that each dose operated thrice. She recovered, and, by taking ten drops for a few successive mornings, succeeded in getting her bowels to act once daily.

R. J., aged thirty years, a powerful muscular man, came under my care on the 24th of January, 1849, for an affection of the urethra. His bowels were habitually costive while resident in London. He was directed to take in the first instance, compound powder of jalap; but, this failing to operate, the oil of Anda was administered instead. After swallowing for three consecutive nights thirty drops as a dose, he obtained a daily evacuation, and needed no further assistance in the way of purgatives.

L. C., aged forty-six years, a female of spare habit of body, subject to piles and to habitual constipation, so that she had rarely a motion within every four days, and while in that condition suffered from severe pain darting from the hip down the leg, procured relief by taking ten drops of the oil at bed time.

A. M., aged twenty-nine years, admitted under my care for mammary abscess. Her bowels were always confined, so that she seldom had any passage except at an interval of eight days. Had taken full doses of castor-oil alternated with compound rhubarb pill, and also a combination of Epsom salts and cream of tartar, without any result. On the 12th of February, 1849, twenty drops of the oil of Anda were prescribed to be taken every night. On the 14th it is reported, that the "doses taken on the 12th and 13th operated seven or eight times each day, without griping, and she felt, generally, better since. The bowels of an infant she was suckling were likewise freely moved, and the stools were green." She was then directed to take fifteen drops which served to insure adequate alvine discharge.

It may be observed, that the average dose of oil of Anda administered was twenty drops, and to secure its entrance into the stomach it was swallowed on sugar. It offered nothing unpleasant to the taste, produced none of that heat in the throat which croton oil creates, seldom occasioned nausea or griping; it rarely operated within a period of two hours, although in one or two instances I have known it act within half-an hour after its ingestion

Towards the maintenance of health it may be laid down as an essential condition, that the *effete* remains of food, and of the spent tissues and secretions present in the alimentary canal, should be evacuated at periodical intervals. Human fæces, of which these may be said to form the aggregate, exhibit all the signs of putrefying matter; they have a putrid smell, and animalcules of the *infusoria* class are developed in them. Hence it may be readily supposed, that if the fæcal excrementitious matter, averaging five ounces daily, be allowed to accumulate and remain for an undue length of time in the body, it must become a source of noisomeness and disease. It is, indeed, well known that some persons, who have passed several days without being thus relieved, exhale a stercoraceous odour. One of the worst forms of putrid fever I ever witnessed, and which eventually proved fatal, distinctly emanated from this cause.* Everybody is familiar with the nuisance created by cesspools when vent is not given to their fetid contents; and does it not seem strange that individuals of moderate intelligence should, from want of a little attention, actually carry for days within them a nucleus of pollution, a cesspool in miniature? It is to inhabitants of populous towns, who lead a sedentary life, and are much confined within doors, that the above remarks especially apply; and without more than strenuously urging here the paramount importance of air, exercise, and diet, in obviating costiveness, I have briefly directed the notice of the Society to a medicinal agent not heretofore employed in this country, and which may be found serviceable in promoting the above purpose.

TO SUBSCRIBERS.

Subscribers in want of any of the back Numbers are recommended to complete their sets. Cases for binding the volumes, price 2s. each, are now ready for delivery.

New Subscribers will oblige by forwarding their Names direct to the Office, 147, Strand, or to the News Agents or Booksellers. All Post-office Orders should be made payable to the Publishers, WM. S. ORR AND Co.

ERRATA.—*In our last, page 91, in the Table of Mortality in the Metropolis, the amount of "Births over Deaths" for the week ending February 17, should have been 272, not 227, as erroneously printed.—In the Memoir of Dr. John Reid, in our last Number, two rather important typographical errors occur. In the first paragraph, 8th line, "philanthropic" should be "philosophical;" and, in the second paragraph, line 7, read "disease" for "dream."*

THE MEDICAL TIMES.

SATURDAY, AUGUST 11, 1849.

We presume there are few of our readers but have seen, with feelings of mingled shame and contempt,—the shame for the Profession, the contempt for their writers,—those numerous letters which daily and hourly parade a new and certain cure for CHOLERA in the columns of the general Newspaper Press.

Absurd and vicious as the system of a non-Medical Board of Health obviously is, still, after all, we may in fairness concede to these authorities the diagnostic skill generally required to discriminate between the living and the dead. And when we find by their published returns, that, beginning with a few scattered but intensely fatal cases,—the heavy drops of the coming storm,—the mortality from this awful scourge of modern times has gradually crept up to its hundreds daily; and when we also find, that, on the whole, amid all possible variety of treatment, the disease offers a fearfully high and rather constant rate of mortality, we can hardly help believing that we have here a very grave disorder, which is, in a large number of cases, and, at the ordinary date at which medical advice is called in, necessarily and inevitably fatal.

Yet, on the other hand, we have almost equal grounds for asserting, that the authorities are deceiving a too confiding public—that it is quite impossible these deaths can have happened, and quite absurd for us to bewail the little efficacy of our art; since or scarcely a day has elapsed without the publication of one, two, three, or more new methods by which the disease may be cured. Why, indeed, do we talk potentially! Rather say, by which the disease *has been* cured.

By each of these methods, the previously dying sufferer has been safely and quickly restored to his wonted health; and it is equally gratifying to observe, that each of them is cer-

tified to by men whom we are forced to believe as honourable as Brutus himself—men whose natural and professional anxiety to save life has no doubt mainly induced them to take the earliest and widest opportunity of acquainting their fellow-creatures with a glorious panacea.

Nor can a captious public complain that the method proposed is arbitrary or inaccessible. So numerous are the remedies, that it is not so much difficult to obtain them as impossible to avoid them. It is scarcely possible to eat, drink, or sleep—to fulfil any function, or pursue any avocation in life, without impinging on one of the cures for cholera. Brandy and beans, catechu, cajeput, camphor, cayenne, chloroform and calomel, opium and olive oil, salt and salts of all kinds, stimulants, sudorifics, *et omne quod exit in-ic*, hot water, cold water, tepid water, rice water, iced water, spring water, and sea water; all of these are alike efficacious. We have for this statement the solemn testimony of men who are morally responsible for the accuracy of what they have written.

Yet cholera continues to rage—death hourly to grasp new victims! But that these subjects are in this country properly removed from the domain of jest, we might justifiably parody the French wit who found himself dying "of ever so many good symptoms" detected by his physicians, and complain that we are dying of too many and too easy cures.

So many are they, that they defy even enumeration, and the only method we can suggest to their enlightened authors is, to collect them into a large book, to be entitled "The Thousand-and-One Cures," in which, whether arranged alphabetically or not, they might at least each receive a separate heading. Indeed, to keep up the analogy to its Arabian prototype, whose bold imagery and flights of fancy this book would far excel, it would be proper to precede each of them by a solemn and reiterated invocation to QUACKERY, the modern Schehezerade that narrates those pleasing but fabulous stories. Choice, by its consultants, would be difficult, it is true; but the *Sortes Virgilianæ* might be revived to determine, not so much the nature, as the mode, of the disciples' fate.

But enough of this. It only remains to us, as one of the organs of the Medical Profession, to disclaim all share of that Profession generally in these unworthy publications; which are, indeed, without excuse. While death, under the guidance of inscrutable Providence, is destroying his hundreds and thousands, the most exuberant Professional enthusiasm can scarcely be at a loss for occupation in the path of duty. And if observation and experiment lead such an one to any new deductions concerning the nature of the disease, or any new suggestion as regards its treatment, his course is still unmistakeable—*to submit his views to the judgment, and for the acceptance of, his Professional brethren.*

Not so the professional harpy: he snuffs his prey from afar, produces his panacea, hunts up his corroborative cases; and while, with a really judicious caution, he declines appealing to his own Profession, he, at the same time, strains every nerve to extort from an alarmed public a reputation which common sense and calmer reflection would induce even them to deny.

But it may be, that there are some of these pseudo-professional authors who have so far purer motives, in that they are more foolish and less knavish than the character depicted above. To these we would point out, more in sorrow than in anger, the grave dereliction of duty of which they are guilty, in aiding these heartless and selfish schemers by their sanction and imitation. Nor can they shield themselves under the notion, that it becomes a duty to publish what they, however mistakenly, imagine to be a cure for this dreadful disease. Do they allow the least possibility of their being in error? Then, why do they eschew the only authority competent to criticise their theory and test their facts? Do they honestly believe in the virtues of their panacea? Then, who would most rapidly diffuse it; the general public, who naturally avoid a doubtfully contagious disease, or their own brethren, daily and hourly among the sufferers? Or, can it be possible, that they wish the public to be their own medical advisers in a disease like cholera?—that they desire the wife, agonized by the thought of approaching bereavement, to judge of their medical logic, or expect the patient sinking under collapse to apply their treatment?

It is almost waste of words to add, that this multiplicity of so-called specifics has further and most mischievous practical tendencies. It converts the ignorance of the many into presumption; it changes decision and promptitude in applying for advice into hesitation and procrastination, and often converts the credulous reader into a confirmed sceptic. Fatal as the disease is, still, in all human probability, it has its set time, during which medicine can effect the best results, up to which delays are dangerous,—beyond which they are fatal.

Were there no other reason, indeed, we should advise one and all, "*stare per vias antiquas.*" It has always been understood, that to justify a Newspaper appeal to the public, requires a commanding professional position, such as no one man possesses in these days,—a simplicity of remedies advised, and in general an inculcation of prophylactics, rather than of treatment. Radcliffe, or Mead, might, in the then state of society, have justifiably thus written; or, in the present day, in a colony where medical advice could not be personally afforded, a similar privilege might be conceded. One would thus excuse a little dogmatism in the medical correspondent of the "Swamp Town Gazette."

This leads us to the close of our remarks. We have but to add, that it is much to be regretted, that, by a mischievous laxity, the general Daily Press should have even unintentionally aided in giving these adventurers the notoriety they so much desire. The contrast between the excellent writing, the admirable management, and the magnificent staff of a paper like the *Times*, and the inane productions thus admitted to its columns, would be ludicrous, were it not melancholy. *Cuique suâ arte credendum*, and we can assure our giant brother, that he would confer a benefit alike on the public and the Profession, by either withholding these publications, or, with his own grim and significant humour, heading them with the word "ADVERTISEMENT." Indeed, we take some credit to ourselves for throwing out this peaceable suggestion, which may reconcile all parties at a trifling expense, and which no quack of proper "Manhood" would refuse to bear. But if this adjustment be declined, we cannot help expressing a wish to see some of these letters in all the glory of their original spelling and punctuation, since we suspect that it might greatly assist in the enlightenment of the public as to their real nature and value.

PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

IN another part of our paper, our readers will find as full a report as our limits will permit of the proceedings of the meeting of this Association, held last week, at Worcester. It was one of peculiar interest on many accounts. It is always delightful to meet old friends,—to talk over old times,—to recal *Alma Mater* and the "joys of the days that are gone,"—almost equally so, to meet for the first time those whose names have been made familiar by their writings,—to compare the man of action with the man of thought, and probably commence an acquaintance, which similarity of tastes and pursuits may ripen into a friendship equally pleasant and profitable to both. Collision sharpens the intellect as attrition polishes the diamond; and the benefit resulting to men, debarred for the greater part of the year by their position and employment from extensive professional intercourse, by these periodical gatherings is incalculable. Lord Bacon says, reading makes a full man, writing an exact man, and conversation a ready man. The public conversation of which the speeches at these meetings consists, is that of all others most calculated to try a man's fullness, exactness, and readiness, and stimulate him to supply any deficiency experience teaches him to feel before subsequent meetings. But this is not all. Good fellowship and good feeling are the result of the two or three days' annual holiday. The mind is released from its cares and the heart opens at the voice of friendship. Little matters of unpleasantness are explained and forgotten; the social morality of the Profession is supported; ignorant pretenders and irregular practices are exposed; and the upright, honourable man finds a reward for honest conduct in that esteem of his associated brethren which may not have been awarded by others. There is also some direct interest in these meetings to those who regard the *fee* as the *summum bonum* to which science is subordinate. Medical men from different watering-places meet, and make reciprocal offers of introduction to patients going from one to the other. The London Professor of some speciality meets his provincial brethren of more general habits, makes known minute proficiency, and probably obtains an increase of practice and its rewards.

To descend from generalities to particulars, we have only to say, that the Worcester meeting was a most delightful one. The cathedral, the battle-field, the china works, and other objects of local interest, amply sufficed to employ

vacant time. The medical men were most hospitable, gave capital dinners to as many as their houses would hold, and offered every possible attention to others. The inns are the good substantial inns of old English towns, and the public feasts were all that could be desired. Then, at seven miles distance was Malvern, with its splendid mountain scenery, and the views of the vales of Hereford and Gloucester; and many a grave Doctor might have been seen last week astride upon the humble donkey, breathing the bracing air of the hill-top, forgetful, for the time, of crowded cities and harassing cares, in the enjoyment of Nature's beauties. The less straight-laced visited the water-cure establishments of Drs. Gully and Wilson, content to gain information likely to be useful to their patients from any source, and were received with cheerful attention, every process being exhibited and explained. But some would not even indirectly appear to countenance irregular practice, and returned to their more genial companions at Worcester.

We have but little to say of the papers and speakers. *The* speeches of the meeting were those of Dr. Hastings, Dr. Conolly, and Mr. Newnham. Dr. Hastings is quite a model Chairman. Dr. Cowan also proved himself to be a ready speaker. The most important papers were those of Dr. Bell and Dr. Sibson, and incomparably the most entertaining that of Dr. Malden, which concealed a vast amount of important information under a humorous mask of the most diverting anecdote. Dr. Bell's paper was unexceptionably good, and we heard but one opinion expressed as to the excellence both of his manner and matter. Dr. Sibson's manner was also very pleasing. He is an excellent and interesting lecturer in point of style; but we, in common with many others, were of opinion, that, when his paper is published and exposed to careful examination, many of his views will appear unsound, and his physiological doctrines far from unobjectionable. This, however, is matter of opinion; and we now beg leave to refer our readers to the report of the meeting, recommending such of them as are able, on future occasions, to be present at similar meetings, by no means to neglect the opportunity of reaping the pleasure and advantage which may be within their reach.

UNIVERSITY COLLEGE CHAIR OF PATHOLOGY.

THE Council of University College have appointed Dr. William Jenner to be Professor of Pathological Anatomy in the place of Dr. Walshe. We do not think a better man could be found to fill that honourable post. Dr. Jenner is already most favourably known to the Profession by a series of very able papers on Continued Fever, which, we have reason to know, have attracted the attention and have received the commendation, not only of many of the most eminent of our own countrymen, but also of the two men who are, perhaps, in all Europe, the best fitted to pronounce an opinion on this subject, viz., Louis and Valleix. So valuable did we, indeed, deem these papers to be, and so much knowledge of the intricate subject of which they treated did they evince, that, some time ago, we induced Dr. Jenner to contribute to this Journal a succession of Articles, which might exhibit to our readers the present state of medical inquiry into the great subject of Fever, and we have the pleasure of being able to state, that we shall speedily commence the publication of those valuable Papers. We have, therefore, a right to congratulate the Council of University College on the choice which has been made, and to anticipate that the enrolment of a zealous and laborious observer, like Dr. Jenner, among the distinguished Professors of that great Medical School, will be followed by results which will be gratifying to all friends of the Institution.

A BOARD OF GUARDIANS' ESTIMATE OF PROFESSIONAL SERVICES.

IN the reign of Claudius, a Governor of one of the Roman provinces exercised his authority in such an oppressive manner that the people sent complaints against him to the Emperor. His flatterers, however, were so noisy in his presence that he was unable to hear what the ambassadors had to say, and, upon inquiring, he was told, by one of the Governor's friends, that they returned thanks for his good administration, upon which the Emperor said, "Let him be continued two years longer in his province." The complaints of Poor-law Medical Officers against the Guardians of Unions, have been repeatedly carried to the Legislature of this country, yet their statements have hitherto been disregarded, and the Union Governors are permitted to exercise their authority in all its original integrity. It is not because they have been falsely accused, that they are retained in power, but simply for the reason, that their policy towards their Medical Officers is supposed to be productive of a great saving in parochial expenditure. The absurdity, the injustice, and the cruelty of this doctrine have been so repeatedly exposed and denounced that we are astonished it should now be credited by any thoughtful persons.

The competition existing amongst the members of the Profession is turned to account by Poor-law Guardians, who, instead of allowing their Medical Officers a fair salary for their services, offer sums which cannot possibly remunerate them. If, under ordinary circumstances, the pay of Union Medical Officers bears no just proportion to the duties required of them, how must it be in seasons when a large amount of sickness prevails amongst the poor? It is true, that, in some districts where the cholera has recently made its appearance, Guardians, with an astonishing liberality, have either strengthened the Poor-law Medical Staff, or have allowed so much extra in every cholera case. This is an act of humanity, and of justice to the poor; and yet there are districts where this spirit of liberality has not been developed.

In the *Times* of Saturday last, a letter is published from Mr. J. T. Mitchell, of Kennington, in which he states, that, during the week ending July 31, he and his two assistants had been summoned to 322 cases of illness among the poor, requiring 1,028 attendances to be given at their own houses, or at his surgery. Fifty of these cases were Asiatic cholera in its different stages, and 141 were cases of diarrhœa and ordinary cholera. For this duty the salary amounts to 100*l*. per annum, which is not quite *three halfpence* for the medicines required by each case, without taking into the account personal attendance. Such an enormous amount of duty kept Mr. Mitchell employed night and day. Nearly every night he was summoned from his bed to attend from three to six cholera patients; and we cannot wonder that he felt his strength give way under the load of Professional engagements. One of his assistants threw up his situation, and another could not be found to occupy his place. The Board of Guardians was accordingly memorialized, and Mr. Mitchell suggested, that all the Medical men of the district whose services were available, should be applied to for assistance; at the same time he proposed, that he should receive 10s. for every case of cholera, not taking into account cases of simple diarrhœa. To this equitable proposition, the Lambeth Board of Guardians paid no attention, and Mr. Mitchell, in consequence, sent in his resignation, which was accepted. He had been the Medical Officer of the parish for eighteen years. *Three halfpence* per cholera case, whether occurring night or day, what a *remuneration!* For this sum there was a large amount of labour to be endured, medicines to be found, and risks to be incurred. Yet, when the Lambeth Board of Guardians is asked for assistance, it is refused, and an old and esteemed Medical Officer allowed to resign his situation if he does not choose to submit to the will of his official masters. We commend Mr. Mitchell for the act of justice which he has done to himself in giving up parochial engagement, and for having made his case known to the public through the medium of the daily *Times*. We hope his Professional brethren will be ready to support him, and that none will be found to undertake the attendance of cholera patients for three halfpence per head. It is time that the laws relating to the Medical relief of the poor receive some alteration. Why should not the Union Surgeon hold his situation as long as he faithfully discharges his duty, and why should he not be fairly remunerated? In the Army and Navy, competition is not allowed to depreciate salaries. These are fixed by the Government, and even a provision made for superannuated Medical Officers. If full justice is to be done to the sick poor, some such system must be adopted in appointing their Surgeons. At least their office should be permanent, and under Government control; their salaries fixed and liberal. The pauper would then have the best security given him of efficient attendance in illness, while those obstacles which now exist to the full exercise of Professional benevolence and skill would be removed.

CHOLERA AND THE ST. PANCRAS GUARDIANS.

ALTHOUGH we should be unwilling to add to the fears of the public, we cannot be blind to the fact, that the progress of cholera in the metropolis during the present epidemic has bidden defiance to the calculations of those best acquainted with its ordinary course. However this may be, the number of deaths weekly is sufficient even now to create just alarm; and, seeing the slight service that remedial agents

have as yet been in checking the mortality, it behoves us to look more closely to prophylactics.

Our attention has been most forcibly directed to this subject, during the last twenty-four hours, by a notice posted on the workhouse of one of the largest parishes in London, that of St. Pancras.

This notice is to the effect, that bodies of persons dead from cholera shall not be admitted into the dead-house of the parish Infirmary. Can such things be, and not excite our special wonder? The Board believe, or act as if they believed, cholera to be contagious—violently so. Its members are no modified contagionists! None dying or dead from the fearful malady shall enter the precincts of the poor-house! They will have naught to do with the unclean thing! This extraordinary dread could only be equalled by the superstitious terrors of the vulgar respecting the leprosy of previous ages, when, we are credibly informed by historians, actions were brought to revenge the contaminations of a relation's corpse in the burial-ground.

In the able Report of Dr. Parkes to the Board of Health, which we reviewed a fortnight since, we were informed, that, at the present moment, all classes of Medical men, (the Gwydyr House Board having retracted its first assertion), are agreed that cholera patients may, and do, give off from their person a something, which, *when it meets with certain external conditions*, may be developed into a poison, capable of inducing cholera in an apparently healthy person. We know, when tolerably diluted, that this poison is practically innocuous: that there is no danger in approaching those labouring under the disease, when the external conditions under which they are placed are favourable—when their houses are drained, their walls and floors cleaned, and free ventilation maintained. But we also know, that, if such be not the conditions in which the patient is placed, fearful may be the spread of the pestilence. Now, what must be the effect of this order of the Board of Guardians? Within the boundaries of the parish over the poor of which they rule, are hovels called dwelling-houses, the stench from which would overpower those not inured to the odours of these *homes*. We lately visited one court in St. Pancras—a specimen of many—in which were seventeen wretched abodes of disease. Fever had visited the inmates. The cottages consisted of two rooms, each about nine feet square. Adjacent to a door opening from one of these rooms was a privy; and under the centre of the huts the drain passed, we were informed, to a cesspool. A drain had burst the floor of one room, in which the people ate, drank, and slept. One of the poor creatures informed us she had but to press the boards to see the filth gush from between the crevices; and that in the night she had at times to leave her bed to inhale from an open window a little somewhat fresher air. We say *somewhat* fresher air; for, in the centre of the court was a large common dust-hole, into which the filth from the closet and drains of the houses just referred to had been poured the day or two preceding our visit, to develope the breath of the pestilence, and to scatter the seeds of death. And here, where every condition favourable, according to the view of the most modified contagionist, for the propagation of cholera poison exists—where are dirt, close crowding, imperfect ventilation and drainage, which it would be a farce to describe as simply imperfect,—where poverty and anxiety have depressed the spirits,—where want has weakened the body,—and perhaps vice has broken down yet another barrier, to favour the inroads of the plague,—here would this sage Board closet the dead with the living. Into these pestilential dens would they bid their Medical Officers enter, to cure, forsooth, their wretched inmates. Let the inhabitants of St. Pancras be up and doing. A notice here and there in a few shop-windows will not remove the disease. It is a subject respecting which they have no time to lose;—a week, a day, an hour may be too late. It is a HOME QUESTION; from these *foci* the disease must spread in every direction, and rich men who dwell in painted palaces are equally interested with these poor wretches who exist in such damp and dismal kitchens, but yet cling to life.

It is a farce for the Board to say they are willing to remove the dead to the churchyard at once. A man dies in the afternoon; must the death-diffusing corpse lie with the living, often six or eight in one room, till the following day? Moreover, we all know how strong is the prejudice against instant interment; it is in vain to say, notice *ought* to be given, and the corpse *ought* to be buried instantly. The husband who left his wife well in the morning, and finds her dead on his return at noon, will scarcely beg that she may be interred that night; the mother who can hardly believe that the infant she saw playing around her knees, literally but a few hours since, is dead, will not consent that ere its tiny limbs are cold they shall be thrust into the pauper's grave. The pestilence must spread far wider among us before the feelings which foster these prejudices will be deadened. We cannot instantly break through old habits. We must bend to them. People are dying in these wretched rooms; their friends will not consent to their instant burial; if, then, these parish Boards be allowed uncontrolled sway, they will, in the plenitude of their ignorance, aid the rapid diffusion of this pestilence, to a fearful extent, over our mighty metropolis.

This city has had warning. We cannot say, as a gentleman, who dwelt in a town not long since decimated by cholera, told us, "it came upon us like a thunder-clap, we had no time to *think* what we should do." Whether the warning shall be of service lies with the people at large, for Boards and Commissioners seem mad or asleep.

Quem Deus vult perdere prius dementat.

THE NATIONAL INSTITUTE.

The Third Annual General Meeting of this body was held at the Hanover-square Rooms, on Wednesday last, the 8th inst., N. Clifton, Esq., in the chair. The Chairman, having briefly stated the objects of the Institute, and the causes leading to them, Mr. Ross, the Secretary, read the Report. This was a well drawn up and valuable document, a calm statement of the case as between the Council of the Royal College of Surgeons and the General Practitioners, detailing the proceedings of the Council of the Institute during the past Session of Parliament in reference to the promised Bill for the regulation of the Medical Profession, the Conferences with the Lord Advocate, the conduct of the Council and Delegates of the Royal College of Surgeons in delaying the settlement of the matters in dispute, and the causes leading to the postponement of the Bill of the Lord Advocate till next Session. In reference to the particular object before the Council of the National Institute, the Report states:—"The Council desires to assist in establishing a College of General Practitioners, with full power to test the qualifications of the Candidates for its Letters Testimonial, in all branches of General practice: any power less than this would not suffice for the object intended, and would not enable the Council to maintain the qualification for General practice at that high standard which alone could secure the respectability and status of their class, and render the General Practitioner competent to fulfil his various and important duties with credit and success."

The various resolutions were moved and seconded by the following gentlemen:—Messrs. Jas. Self, J. Bowling, Thomas Martin, of Reigate, J. Propert, Jas. Clayton, Robert Tanner, George Robins, Richard Wallace, — Nicholson, G. J. Squibb, and H. P. Fuller; the last resolution suspended the election of Officers and Council during the ensuing year, in order to retain the services of gentlemen who had been so active in the cause of the Institute, and so thoroughly acquainted with all the circumstances in which it is placed.

Next week we shall return to the subject.

THE OPERATIVE SURGERY OF JOHANN FRIEDRICH DIEFFENBACH.

Edited by Dr. BUSHNAN and Mr. URE.

The suggestions of several esteemed friends, and the marked satisfaction with which this Edition of Dieffenbach's Surgery has been received by the Profession, have induced me to depart, in some degree, from the plan with which I commenced it. I propose, then, to render the Work still more complete and acceptable, by the co-operation of a practical Surgeon—of one not only deeply read in the literature of his science, but ably practised in the manipulations of his art. The services of such I have happily secured; and for the future the Work will be published under the joint Editorship of myself and Mr. URE, of Bloomsbury-square, Fellow of the Royal College of Surgeons of England, and Surgeon to the Westminster General Dispensary.—J. S. B.

(Continued from page 96.)

CHAPTER II.

SUTURES.

Sutura Vulnerum Cruenta.

Suture is the method of uniting wounds by means of stitches. It is applicable to all cleft wounds of the skin and subjacent parts, of which the edges cannot be kept in intimate contact and healed by means of adhesive plaster and a roller, especially to those of the face, eyelids, nose, ears, mouth, and cheeks; to extensive longitudinal and oblique gashes of the trunk and extremities; to penetrating wounds of the trachea, thorax, and abdomen; and to congenital or accidental fissures of the eyelids, mouth, or perineum, covered with epithelium. It is the only mode of union in wounds, or solutions of continuity in moist surfaces invested with serous or mucous membrane, as in lesions of the tongue, congenital clefts of the palate, wounds of the windpipe, penetrating wounds of the chest and abdomen, of

the bowels, in recent and old fissures or openings in and upon the female and male parts of generation which communicate with the bladder or urethra. Its employment is contra indicated by the presence of acute inflammation, or of suppuration in the wounded surface.

Sutures occasionally derive their name from the situation in which they are inserted; as, for example, the hair-lip suture, palatal suture, intestinal suture, perineal suture, the vesico-vaginal suture, and so forth.

Of the varieties of sutures introduced into surgery, three only deserve notice. Each has its value, and cannot, or only under particular circumstances, supersede the other. They are as follows :—

1. The interrupted, or knotted suture.
2. The twisted suture.
3. The subcutaneous suture.

The two first lie half within, half without the wound; the third is completely hidden beneath the integument.

I. THE INTERRUPTED, OR KNOTTED SUTURE.

Sutura Nodosa.

This is executed by the help of a double-edged needle, curved on the flat, and a waxed double silk thread. The wound is to be previously cleansed of blood by allowing water to trickle from a sponge, all bleeding arteries having been first secured by ligature or torsion. The surgeon then taking the needle in his right hand, with the thumb upon the middle of the concave surface, the fore and middle fingers upon the convex surface, and the thread thrown over the back of the hand, makes a stitch one, two, three, or four lines distant from the margin, according as the wound is large and deep, or small and superficial, from without inwards through the skin, commencing at the left end first; carrying the needle onwards, he makes a second stitch, corresponding to the former, from within outwards. He then, after tying the knot, cuts off the ends of the thread. The adjustment of the first and second knots is accomplished with the forefingers, while the ends are held with the closed hand. Firm pressure is then exercised with a sponge upon the wound to squeeze out any oozing blood; and the remaining sutures inserted at suitable intervals, both edges of the wound being pierced at one stroke. Any ligatures that may be present are to be placed at the angles. Lastly, long narrow *slips* of plaster are to be applied betwixt every two sutures, one always upon the edges of the wound.

For the coaptation of small superficial wounds in the skin, thin needles and thread are eligible. Where the skin is very delicate, as in the eyelids, the point selected for the insertion of the suture is to be taken up with fine hooked forceps, and the needle in that manner pushed through. Care must be had to guard against any spasmodic inversion of the lid. Should this happen, it is to be retracted with forceps, and the raw edges are to be steadily pressed together with the finger and sponge.

Large deep wounds must be stitched with stronger needles and several layers of thread, the punctures made at least half an inch to the side, and the base of the wound, when it cannot be approximated with the skin, perforated, and included in the suture. Otherwise, a cavity is left, in which blood accumulates. It is a matter of indifference whether the first sutures are inserted at the angles, or at the middle of the wound; the last, however, is preferable. The sutures must not be too far apart, so as to allow the edges to gape; or, on the other hand, too closely crowded together, lest they induce inflammation, and thus prevent healing by the first intention.

In introducing sutures into cavities or fissures, where it is impossible to use the fingers to draw through the needle, recourse must be had to the so-called *porte-aiguille*, or to forceps of different size and length, with very short blades and long handles, as, for example, in wounds of the tongue, vesico-vaginal fistula. The most convenient form is that resembling a dentist's forceps, for the extraction of the superior incisors. The needles for stitching within cavities must have a considerable bend in the middle. Instead of the *porte-aiguille*, hafted needles are sometimes employed.

It was stated above, that in the intervals of the sutures, long, narrow strips of plaster were to be laid upon the lips of the wound, and made to adhere firmly to the skin. Where the latter is delicate, the plaster may be spread upon fine linen, but if the wound be large, on strong unbleached linen or calico. In applying the strips of plaster, the parts ought to be tightly pressed together, and short ends laid upon the interspaces. To counteract pressure upon the knots, two strips are to be placed parallel to the lips of the wound, crossing the others at right angles, in order to elevate the sides. It was formerly the practice to leave portions of the wound exposed to the air, and to use few adhesive strips, but the subcutaneous operations have shown that suppuration is especially prevented by exclusion of air. Tying with slip knots is not advisable, neither tightening the thread in case of slackness, nor unloosing it in case of inflammation. The suture must be left untouched. In minute cuts of the face, as in the eyelids, no plaster should be applied.

The first condition in furthering primary union, preventing the threads from dividing the skin, and the accession of suppuration, is complete repose of the part. Compresses and rollers cause heat and pressure, and disturb the healing process as surely as cold applications, when the integument is lax and flabby.

The first threads are commonly withdrawn upon the third, the last upon the fourth or fifth day. The strips of plaster are not to be meddled with, for otherwise the wound may gape, and fresh strips do not brace like the former, glued, in a manner, to the skin with blood. The short end of the thread is to be seized with forceps, a slight to-and-fro movement made to detach the circle, and then with the blade of a scissors, introduced close to the knot, the suture severed, and withdrawn in the line of the wound. Additional strips of plaster are finally interposed betwixt the others.

Where, owing to the number of sutures, the lips of the wound become much inflamed, very turgid, and red, early removal of one or two here and there is indicated, so as to lessen the amount of extraneous matter in the wound. A flow of blood from the punctures is beneficial in warding off the risk of suppuration. This ought to be encouraged by dabbing with little bits of sponge, soaked in warm water, held in forceps. No moisture should be applied beyond. The wound may be covered up after the hæmorrhage has ceased. If suppuration sets in, the sutures lose hold, begin to cut, and gradually draw the lips of the wound obliquely asunder; hence, instead of promoting union, they leave behind unseemly scars. Under such circumstances, they must immediately be taken out, except in parts where the wound is healed from below. Into the gaping and suppurating aperture a little picked lint is to be laid, and all further divergence of the margins checked by strips of plaster. When the discharge of pus is abated, and the chasm materially contracted, the edges may be more closely approximated. Even with wounds, which have healed by the first intention, it is prudent to allow the plasters to remain until the textures are consolidated, else the surfaces get drawn apart, and assume the appearance characteristic of repair by the process of granulation.

II. THE TWISTED SUTURE.

Sutura Circumvoluta.

This implies the perforation of the edges of a wound with needles, and intwisting of the same with thread.

For this purpose the so-called insect needles are employed, of a length and thickness suited to the wound. For small wounds of the eyelids, they ought to possess the length and tenuity of fine pins; and for connecting the soft parts, after the extirpation of cancerated lip, the length of the finger, and the thickness of a large darning-needle.

The mode of procedure is as follows :—In deep gashes the surgeon takes hold of one edge and raises it a little up; he then pierces it slantwise, at a breadth of from one to six lines, from without inwards, carries the needle over the base of the wound, turns the point obliquely upwards, and perforates the opposite edge, in an inverse direction, from within outwards. He next winds round the needle one or more threads of cotton wick. The first turn is a circle, the second a cross upon the insulated portion formed by the circle, and which it serves to press down. This is repeated alternately, until enough is wound round, whereupon the two ends are tied. The proper degree of firmness is denoted by the natural feel of the part: too feeble counter-pressure diminishes the chance of union; too much, again, provokes suppurative disruption. If the integument included betwixt the ends of the needles is entirely covered with the threads, the two ends are to be bent a little, whereby the threads are rendered somewhat looser, the contact of the surface of the edges better maintained, the division of the needles facilitated, and the pressure of the wire on the skin prevented. By the aid of small cutting pliers, the ends are to be severed about a line's-width from the threads, after which the latter are to be cut off close to the knots.

Other methods of winding the thread are less eligible, because none affords so equable a distribution of pressure as that just described. Thus, if merely circular turns be employed, a kind of islet is formed in the middle, which swells up, projects convexly, and is prone to gangrene or suppuration. Moreover, the want of adequate pressure is injurious.

The simple crucial twining of the thread is, on the other hand, alike faulty, because violence is done to the subjacent skin, which leads to mortification, and, eventually, to a slant and suppurating fissure. No general rule can be premised as to the requisite number of needles, or the interval between each respectively. It is best, however, to introduce them first at the centre, and thence proceed towards the angles.

Every needle, so soon as inserted, ought to have the thread wound round it, and, not until the knot is tied and the ends cut off, a second introduced. The passage of all the needles as one act, and the intwisting of the thread as another, is troublesome, dilatory, and injurious. The bleeding is disturbed, the threads get entangled, and the punctures do not accurately correspond.

The intertwining of the thread from one needle to another, as occasionally resorted to in hare-lip operations, is open to the above objection. It has, moreover, this disadvantage, namely, that when the continuous turns are made, sometimes like the horizontal and sometimes like the vertical figure of 8, the needles become so intimately bound together, as to require to be simultaneously withdrawn,—a thing not always possible, as it is often expedient to remove them at various times. To this it might be urged, that the blood-crust agglutinates the threads so firmly, that a part of the apparatus might be taken away without detriment to the remainder. This is often, but not always the case; for, after fomenting with water or solutions of lead, the thread is apt to come unwound, and leave the needle free.

Another effect of the continuous thread is, that the intermediate turns tend to approximate the several sutures. This may be immaterial as regards a simple wound, even beneficial in long wounds, as tending to lessen them, but positively injurious where the shortening leads to deformity. And such must inevitably happen in oblique sections of the eyelids, *alæ nasi*, and in hare-lip. Every cicatrice determines some contraction, as being shorter than the wound, which is increased by the intermediate twisting of the thread; the result is, that the eyelid cannot shut properly, the *ala nasi* is upraised, and the lip much shortened.

The needles are withdrawn when the wound is nigh healed,—the first, usually upon the third day; but, should there be much inflammation, on the second day, bleeding from the punctures being meanwhile encouraged. The last are usually taken out off the fifth day. This is most readily accomplished by the side on which they entered. From neglect of this trivial point, risk is incurred of tearing asunder the lips of the wound. The extremity of the needle is grasped longwise, like a divided

artery, with broad forceps, and loosened from its hold by a half turn on its axis, first to the left, then to the right. The points of the left thumb and forefinger subserve for steadying, while the needle is withdrawn in a slight curve. Besmearing with oil is apt to dissolve the recent union. Previous moistening of the threads with tepid water is to be deprecated, for it causes a puffing and contraction, which impede the outward passage of the needles.

The Carlsbad insect needles have availed me for the twisted suture, from the earliest period of my career. I have consumed about a hundred thousand, learned to estimate their value with each new operation, and to their instrumentality owe my best results in plastic surgery. In the year 1824 I contributed to the Eighth Volume of Hecker's "Annalen," a brief memoir on the "Modified Twisted Suture with Insect-needles, as a rapid means of Cure in Wounds of the Face." Since then I have strenuously recommended the practice to my professional brethren.

It has been imputed to the insect-needles, that that they are difficult to introduce and prone to bend. The genuine Carlsbad, however, which are very sharp and elastic, if lubricated with tallow, glide rapidly through in skilful hands. It is not easy, indeed, to force them into hard cicatrices; but here thicker needles may be selected. One great advantage they present is the ease with which the ends can be snipped off; and they leave no marks in the skin, as alleged. Fine sewing needles have been proposed for the same purpose. These certainly penetrate better, but are apt to break, and do not bend, which is desirable for ensuring contact of the edges of the wound, and preventing the ends from pressing against or hurting the skin. When cut through, the fracture is sharp, not smooth, consequently prone to injure.

COMPARATIVE MERITS OF THE INTERRUPTED AND TWISTED SUTURE.

These two varieties are totally dissimilar in action. In the interrupted suture, a ring of thread encircles a minute portion of the skin, which it confines, and when firmly applied, strangulates and divides, as in the ligation of an artery. For the latter, division of the texture is proper; for the former, not so. Hence, the interrupted suture ought not to be too tightly drawn, or remain beyond a limited time; or, on the other hand, left too slack, because the intervening clot of blood will operate as a foreign substance, and counteract union.

The twisted suture, again, acts in virtue of the mutual pressure and counter-pressure of the needle and thread. The lips of the wound are not held together by a circle of thread, but by compressure of the surface against the subjacent needle. Within the annular thread circulation is impeded. Here, on the contrary, it proceeds uninterruptedly, and is alone effected by the strain of a waxed silken thread. Cotton-thread is not likely to cause any strain. It is no uncommon thing to introduce alternately an interrupted and twisted suture, or two of the former to one of the latter, and inversely, or three to one. In all angular situations, in the angle betwixt the nose, cheeks, and lip; in that betwixt the nose and eye-lids, and betwixt the buttock and perineum, I seldom resort to the twisted suture; in the vagina only to the interrupted; because the insertion of the needles is laborious, and the ends inevitably press inwards. I dispose the sutures again alternately, where the internal spaces are not exactly conjoined.

With respect to any general rules touching the adoption of the one or other method, it may be laid down that the twisted suture is adapted for the head, with exception of the parts covered with hair, where, indeed, stitches are rarely admissible; for the trunk, sometimes the twisted, sometimes the interrupted suture, according to the lesion; for the extremities of the body, only the interrupted suture. In reference to the face, it is not merely the attainment of an imperceptible cicatrice which decides the preference in behalf of the twisted suture, but the resulting fixation of the facial muscles, as, for example, of the mouth. As regards the trunk, the seemliness of the scar is of secondary moment, also the tardy healing of the wound; but in penetrating wounds of the chest or abdomen, the twisted suture is often a means of saving life, where the interrupted suture, or other plans of adhesion, would not avail. It is by preventing, in such cases, the entrance of air, that danger is averted, and a speedy cure effected. In abdominal wounds, moreover, the chance of the intestines getting interposed betwixt the inner edges and producing hernia, are obviated by the procedure in question.

REVIEWS.

The Manufacture of Sugar in the Colonies and at Home, Chemically Considered. By JOHN SCOFFERN, M.B., Lond., &c., &c. 8vo. Pp. 160. London: Longman and Co.

We have derived much pleasure from a perusal of Dr. Scoffern's treatise on the Manufacture of Sugar, and regret that the subject is one that does not admit of a lengthened analysis in a Medical Journal. To the manufacturer and general reader this work must prove extremely interesting, giving, as it does, a concise account of the methods in use for the refining of sugar, and pointing out the many difficulties that refiners have to contend with in the various stages of their operations. The loss sustained in these is so great as scarcely to be believed; hence it becomes a question of the utmost moment, what can be done to remedy these evils?

"The amount of sugar in sugar-cane juice varies from about 17 to 23 per cent.; whilst, according to the almost united testimony of all observers, 7 per cent. of sugar (about one-third) is something more than the average quantity obtained; and this, too, not in a condition of chemical purity, but admixed with numerous foreign matters."

The juice is obtained by crushing the cane in a mill between rollers; and the object of the manufacturer is to separate the impurities contained in the juice.

"This separation must not be effected beyond a certain extent, or the sugar existing in the cane juice obstinately refuses to crystallize on being evaporated; a circumstance not peculiar to sugar alone, but of almost universal occurrence in parallel cases. To defecate merely, or effect the separation of impurities from sugar containing juices, is but one portion of the problem to be solved. The defecating process must be effected without destruction to the sugar, and by an agent that is so perfectly under control that any excess of it, above the quantity necessary to defecation shall be easily removable. For practical purposes another and a most important condition must be achieved;—the whole must be effected within the limits of a remunerative cost."

Having spoken of the process of claying as practised, by the Brazilians, and the West Indian method of using lime as a defecating agent, and various other proposed methods, and pointing out their faults which it does not seem easy to remedy, our author says,—

"Very far superior to all other agents as precipitants for the vegetable impurities of natural sugar containing juices,—as also for the impurities existing in Muscovado sugar,—are the acetates, particularly the basic or subacetates of lead."

Certain difficulties presented themselves to the use of lead which were sufficient to prevent its employment:—

"The reasons of this failure, in the employment of lead salts, for the purpose indicated, are various, as will be presently recognised. The first problems to be solved are these:—either to use the lead salt in such exact proportion to the amount of impurity with which it is intended to combine, that both shall fall down in combination, and be capable of removal; or to add a known excess of lead salt to the sugar solution,—to separate the precipitate caused by filtration,—then to throw down from the filtered liquor all the remaining lead by means of some precipitating agent not productive of injury to sugar; and as a subsidiary problem,—to remove the acetic acid liberated from the lead, either as an insoluble compound, or to combine it with some body that shall neither be injurious to sugar or to health, and separable, if possible, by the process of drainage."

The lead must be added in excess, and this excess must be removed from the filtered solution. To accomplish this presented a difficulty which, according to Dr. Scoffern, we hope has at length been removed. Hydrosulphuric acid gas was found to destroy the sugar while it removed the lead. Sulphuric acid must be added in an exact proportion, as it either leaves lead, or else itself causes chemical changes. Messrs. Gwynne and Young proposed diphosphate of lime, and took out a patent for their process; but which was found inapplicable on the large scale on the score of expense and uncertainty. In 1847 Dr. Scoffern ascertained that sulphurous acid gas was likely to supply the desideratum, and from the success that has attended the various trials that have been made with it, we think it likely that ere long it will come into general use, provided the public can surmount the very natural prejudice against swallowing a condiment, that has been previously treated with solutions, so notoriously deleterious, as those of lead. In the preface he states that he has succeeded in extracting by his process more than 20 per cent. of crystalline sugar from cape-juice supplied from the estates of the Messrs. Hardy, of Cork. We regret that our author has thought proper to refer us to another work for the steps of this process, instead of giving a short account of it, as might easily have been done in the one before us. In conclusion, we would express our satisfaction at finding a member of our profession directing his attention towards improving and rendering cheaper an article that has almost become a necessary of life.

Fruits and Farinaceæ the Proper Food of Man, An attempt to prove, from History, Anatomy, Physiology, and Chemistry, that the best Diet of Man is derived from the Vegetable Kingdom. By JOHN SMITH. London: Churchill. Pp. 342.

The Author divides his work after the immemorial fashion of all orthodox writers into three parts. The first containing the evidence from the character of the "Original Food of Man;" the second, "Natural" Food, and the third the "Best" Food.

Mr. Smith commences his argument by a reference to the original condition of man, and, after sundry allusions to the Book of Genesis,—to the longevity of the Antediluvians—to the instinct of man, as leading him to the selection of "fruits and farinaceæ," comes to the evidences afforded by comparative anatomy. Here we of course meet him on something like debateable ground. But to lay the emphasis our Author does on the natural condition of man, is as if we were going back to these primitive times. The undraped mythus of our First Parents is all very well in its way; but it would be very obviously pushing the thing a little too far if a general ordinance were to issue now, for the first time, for all persons to follow Nature in the same way, and cut short their tegumentary investments. To live solely on nuts and pomegranates we think not less absurd.

In the second part of his argument, the Author sets out with the somewhat singular position, that man is an "extinct species," and his natural history *to be* quite unknown! While, in another part of his Work, he takes him again out of the Dodo class, and puts him alongside the hog and ourang outang. There is no analogy, we are also not a little staggered to learn, between the general organisation of man and the carnivora—the writer, with no little ingenuity, regarding all such evidences against his theory as the "shadings off" of one particular type,—the carnivorous into the herbivorous,—Nature, as is her wont, doing nothing by starts.

"An organ which is strikingly characteristic in one class," quotes our Author, "disappearing by successive gradations through several other orders, till it finally vanishes, or becomes merely rudimental." In man, therefore, the cuspids may be regarded as a form of transition between the incisors and bicuspids, having no reference whatever to the flesh-eating propensity. The articulation of the lower jaw also in man makes against his being carnivorous, Mr. Smith assures us; but we would ask, does it make against his using a mixed diet? Certainly not. Does the wonderfully beautiful arrangement of the pterygoid and masseter muscles point to nothing,—the relative length of the intestinal

al, &c.? This we take to be about the weakest part of the book.

Mr. Smith strengthens his argument from the inference of the senses, and quotes several striking facts. The sight of dead flesh would naturally scare man from its use; and, reverting to his old acquaintance, the Book of Genesis, says, with some complaisance, that when the woman *saw* that "the tree was good for food, and *pleasant to the eyes*," &c., "she took of the fruit and did eat, and gave also to her husband." But here, under favour of our friend, we would say, that Eve was doing wrong, and we should take her "*varium et mutabile*" as a very doubtful guide.

The evidences from the "moral feelings" (p. 86) we regard as thoroughly puerile, even though the cruelties of Smithfield are revolting in the last degree; and the sledge-hammer, worked by steam, hinted at the other night in the House of Commons, anything but a pleasant matter to think about. We should as soon, however, think of arraigning against vegetarianism the multipled miseries of the "agricultural interest," or the accident that befel Don Quixote when he meddled with the windmill; the subject is one not to be eked out by such accessories. We are quite content to believe, that man is intended to relish his "Nuts and Apples,"—a better name, we think, by the way, for the book than its present alliteration. Yet that we should shut our eyes to the fact, that, according as he rises in the scale of civilization, he stops "digging for pignuts," and instinctively searches out his food in a more economic form, is perfectly without excuse.

In Norway and in Arabia horses are fed on fish, and every one may have observed that a parrot may be brought to feed on flesh. Yet here it is quite obvious we are doing violence to Nature. We are not, of course, so absurd as to deny, that our present code of dietetic rules is not artificial in the highest degree. Yet that there are certain admixtures of vegetable and animal food that we instinctively crave, is equally undeniable; and if instinct is to be consulted at all in the matter, the members of the Beef-steak Club are as good exponents of the doctrine, as our great mother Eve by the silver fountains of Eden.

Though she has placed him at the top of the scale, Nature has not formed man different from other members of the sentient creation, and to study him properly we shall study him in his totality. She has not pulled down the old structure, and reconstructed it on a different plan; she has merely added "Corinthian capitals and Doric columns," as observed by Sidney Smith, to the original edifice; and, above all, she has given him an intellect to correct the errors of his instincts, and a status in the social scale which he should not willingly lose sight of.

The third part of the work on the "best food of man," is, perhaps, the most interesting of the three into which the book is divided. That vegetables contain all the elements necessary for the complete nutrition of the system seems not very difficult to prove, after the late researches of Liebig and Mulder: that the uses of vegetable diet is nothing new, too, he need scarcely go back to the days of Pythagoras and Plutarch, as the Author does in these chapters, to prove. We should not like to build much, however, on the fallacy of standing on the "*antiquas vias*" of the world; and as to vegetables containing all the elements of nutrition, milk does so, perhaps, in an equally eminent degree. We shall not recommend our friends, however, to live exclusively on milk, no more than we should exclusively on meat,—a due admixture of nutritious and innutritious matters of vegetable and animal diet being the exact mean towards which man's organization clearly points.

The diseases originating in abuse of animal food are next indicated.

"Food in excess," says Dr. Clarke, "or of a kind too exciting for the digestive organs, may induce tubercular cachexia—a circumstance not sufficiently attended to—nay scrofula."

Abernethy says—

"Animal substances are changed into a putrid, abominable, and acrid stimulus."—P. 189.

All which, it seems, was further verified by Sir Edward Barry, who prevailed on a man to live on partridges without vegetables, but who, after eight days, was obliged to desist, in consequence of incipient putrefaction. Here, however, it is not difficult to perceive that it is from the *abuse*, not the use of animal food, our Author argues—a very old and time-worn fallacy.

Some valuable observations are made on the injury likely to accrue from the continued use of highly *concentrated* nutritious substances, and the case of Dr. Stark is mentioned, who made some experiments of a very curious nature, among the rest some on himself, as to his power of living on oil, and flour, and gravy, and such like concentrated substances, but died in the course of nine or ten months, in the most miserable state. The people of Kamskatka, if we are rightly informed by travellers, show more sense than this, mixing sawdust very sensibly with their oil; indeed the thing would seem to require no experimental demonstration, and why it should be brought by our Author, into his great armoury of facts we cannot divine.

The chapters on the experience of nations and individuals, though somewhat picked out, and consequently one sided, contain many valuable facts also, and, as showing a state of deprivation of the ordinary necessaries of life rather than the normal condition of the human family, not uninstructive. The Russians, for instance, exist (or the most part on black bread, pickled cucumbers, and mushrooms; butcher's meat is nearly unknown. In Norway, the peasantry exist on this same black bread, with thin slices of meat dried in the wind. The Poles and Hungarians exist on oaten bread and potatoes. In Spain, after the ever memorable example of Sancho Panza, we suppose the peasants eat nothing but onions and brown bread;—the Greeks eat figs and dates;—the Turks, at Constinople, fish and figs. Among the Hindoos, the three higher castes are prohibited from the use of flesh meat; the fourth are allowed the privilege. The Pattamars, a caste that carry letters and undergo frightful fatigue, subsist on a little boiled rice. The Chinese live on rice and fruits. An African race, the Kroomen, luxuriate on yams and palm oil;—the inhabitants of Mexico on maize;—the Affghan lives on bread and curds; yet, according to Sir Francis Head, "he will undergo as much fatigue, and exert as much strength as the porters of London, who are fed on flesh and ale; neither is he subject to their acute and obstinate disorders." The Spaniards of South America live on vegetables; they are, perhaps, as equally strong.

These are no doubt striking facts, and not to be lost sight of by the practising physician; in giving advice as to the bringing up of children, &c., a proper preponderance of vegetable over animal food, being more likely to do good than the opposite, and *vice versâ*.

Indeed, in this point of view we look upon Mr. Smith's book as one of no little practical value, and likely to do much good, exhibiting the *possibility* of human existence on "Fruits and Farinaceæ," and the injury likely to arise to the human constitution from an exclusive adherence to animal diet, evinced in the several diseases, especially of the blood and renal system; the very paramount importance of a mixed diet is as fully shown as its warmest advocate might wish.

Mr. Smith, in conclusion, recommends the adoption of his mode of diet to be gradual.

THE INADEQUACY, IMPOLICY, AND INJUSTICE OF THE PRESENT SYSTEM OF POOR-LAW MEDICAL RELIEF.

[To the Editor of the Medical Times.]

SIR,—To diminish the rate of mortality, and the amount of sickness and disability among the poor, by improved arrangements for the speedy detection and efficient relief of their diseases, is a matter of such vast importance to the welfare of all classes of the community, that any suggestions towards the institution of a system of Medical aid superior to that which prevails under the Poor-law, cannot fail to interest those who are endeavouring to promote the public health.

After a long experience of visiting the sick of a large Union, I am satisfied that the present method of administering Medical relief is very unsatisfactory, both to the poor and to the Medical Officers; and it is my sincere hope, in bringing the question before the public, that some attempts will be made to place this department on a better foundation.

The principal evils of the present system of Medical relief arise from the circumstance of the Medical Officers not being responsible to a properly-constituted Medical authority. They are annually elected by Boards of Guardians, who are profoundly ignorant of everything that relates to Medical science; and they are subject to their control and to that of the Poor-law Commissioners, who are equally uninformed upon Medical subjects.

Now, if in the Medical department of the Army and Navy, the supervision which is exercised by the Director-General and the Medical Inspectors, has proved to be so efficient in reducing the amount of mortality and improving the physical condition of the men, it surely is a duty incumbent on the Government to appoint similar officers for the regulation of attendance on the poor. Medical men would more readily listen to advice from one of their own Profession, and feel greater confidence, that in all cases of alleged neglect, justice would be done to them, than at present, when subject to the caprice of those who are necessarily incapable of judging of the merits of any Medical question.

If a Medical Director-General of the Public Health, and a staff of Medical Inspectors subject to his control, were appointed, (wholly apart from the Poor-law Board,) to whom were intrusted the supervision of the district surgeons, we should doubtless soon experience a great decrease in the amount of sickness and mortality of our labouring population, and proportionate saving in the Poor-rates and other public expenditure. We should also soon cease to hear the bitter complaints of the Medical Officers on being compelled, in order to retain their private patients, to attend paupers and supply them with all necessary drugs and appliances at 4d. to 6d. a case, (as is really the fact in some Unions.)

The re-arrangement of the Medical districts throughout the kingdom would be an essential feature of any thoroughly-amended system. In rural districts, the separation of private practice from Medical poor attendance might not be practicable nor desirable; but in towns and crowded populations, for the sake of the food, it would be advisable to make the Medical Officers independent of private practice. Under the present arrangement the Medical Officer incurs the risk of losing his only means of support, namely, private practice, by attending to a pauper case when his services are required by a person in good circumstances. The poor then suffer from the delay, and the expense, indefinitely increased by the protracted illness of the pauper, must be defrayed by the ratepayers. If, however, it should be thought that the duties of attending to the sick of a moderate district are not sufficient to engage the whole of the time of the Medical Officer, he might superintend the registration of births and deaths, in order to secure greater accuracy in the returns than at present; and, as a surer preventive of crime, he might be required to verify the fact and cause of every death within his district.(a) The regular house to house visitation, recently adopted with such marked success at Dumfries, should also be performed under his supervision. The vaccination of the district, and other prophylactic measures and sanitary duties, which may, under the Public Health Act, have to be performed by District Medical Officers, would also form parts of his duties. Thus his time might be fully and profitably employed.

Most persons are now agreed that the cost of the drugs for the use of the poor ought to be defrayed out of the local rates; and in some Unions, I am happy to say, the guardians have adopted this system, it being manifestly unwise to place the duties of the medical officer at variance with his interest as regards the supplying his patients with expensive remedies. It is a fact, that in some Unions the excessive expense of dietary recommendations arises mainly from the necessity felt by the Medical Officers to charge the cost of the remedy on the public. They are compelled to treat certain cases by prescribing meat, brandy, and porter, instead of furnishing, at their own expense, ether, quinine, and sarsaparilla. The poor

(a) The Guardians of the Whitechapel Union have recently expressed an opinion, that the District Medical Officer may insist upon visiting every case of death before giving a certificate. The Legislature ought to make it compulsory upon a Medical Officer to certify as to the fact of death in every instance.

generally are aware that the Union surgeons are badly paid; they therefore naturally infer that their medicines are of little efficacy, and in very many instances they refuse to take them. Nor is this to be wondered at when the mode of administering medicines at an hospital is compared with that adopted by the majority of Union surgeons. By law, the poor are entitled to receive medical advice and medicines when suffering from sickness, and both ought to be of the best description, otherwise the boon become a mockery. In towns, therefore, dispensaries should be made use of, or opened at the public expense, for the supply of medicines to the out-door poor.

With regard to the in-door paupers, the same care should be taken of every patient in a workhouse as in a hospital. Each case should be entered on a paper suspended at the head of the bed, and the medicines and diet which are required for the invalid should be noted on the same paper. There should also be a resident dispenser in every workhouse, who should be required to see that each patient has his medicine properly prepared and labelled, and be in readiness to attend to every case of emergency until the arrival of the Medical Officer; for cases requiring immediate assistance are of frequent occurrence in every large workhouse; besides, persons are brought by the police to the workhouse in a state of insensibility, and some have died before Medical aid could be procured. The Medical attendance on the workhouse ought always to constitute a distinct appointment from that on the out-door poor.

Some pseudo-economists may object to the amendments above suggested, on the ground of expense but, if they were faithfully carried out, I am firmly of opinion, that so far from proving more burdensome to the rate-payers, they would soon be found to diminish our parochial expenses.

The propositions briefly stated in this letter embody the main principles of Medical poor relief, long since advocated by Mr. Rumsey, of Gloucester, and Mr. Ceely, of Aylesbury, on behalf of the Provincial Medical and Surgical Association, and therefore have received their concurrence. Nothing short of the alterations now suggested, in our opinion, is likely to prove satisfactory to the public, the poor, or the Medical profession.

4, Ali-place, 28th July, 1849. JOHN LIDDLE.

UNIVERSITY DEGREES.

[To the Editor of the Medical Times.]

SIR,—In the *Medical Times* a short time since, is a letter on the subject of University Degrees, from "M.D. et Chirurgus," in reply to that of a gentleman who had drawn attention to the advantages offered at Aberdeen and St. Andrews to General Practitioners desirous of a Medical Degree. The "M.D. et Chirurgus" is very severe on your former Correspondent for his (alleged) ignorance of the subject, especially in reference to the *English* Universities, and "avails himself of the opportunity to set him and many of your readers right in that respect." In an authoritative manner, he states the course of Medical Education and Degrees at Cambridge, intermingling many sneers at the system which he details. To judge by the acerbity of his criticism, one would never suppose this corrector and spontaneous informant of others to partake so largely of the ignorance he condemns,—"the ignorance on this subject that is very prevalent in society."

But surely he might have inquired of some Cambridge acquaintance (if he have any) what the system is, before he ridiculed it; or he might have referred to the *Cambridge Calendar*, before making himself ridiculous by his blunders. He would not then have stated, that "the student may go out in Medicine within three years. To *go out* in Medicine, or in Law, is what is called, in the University, *degrading*, the degree being inferior to the B.A. degree." The fact is, that the student must have been entered at the University five complete years before he can *go out* in Medicine, *i. e.*, take the degree of M.B. During three of these years he must have resided in the University; the other two being spent at any good Medical School. The term *degrading* was never applied to going out in Medicine until your Correspondent used it; and the degree of M.B. is not inferior, but superior, at Cambridge, to that of B.A.

Again, "M.D. et Chirurgus" states:—"As to the examination for the Medical Degree, he (the candidate) has to do with but one Examiner, the Regius Professor of Medicine." On the slightest inquiry, this gentleman might have ascertained, that the candidates for the degree of M.B. are examined, not only by the Regius Professor of Physic, but also by the Professors of Anatomy, Chemistry, and Botany, and the Downing Professor of Medicine, and have to produce certificates of hospital-attendance, &c.

Moreover, he states:—"Upon ten years' standing the Bachelor takes his degree (of M.D.) as a matter of course, upon payment for it, &c." "He has not however, to undergo any further examination or any trial, beyond a laughable monkish ceremony, descended from the Medieval Customs."

These are as exact as his other statements. M.B.s of more than five years' standing may be candidates for the degree of M.D., but cannot obtain it unless they have passed a practical examination by three Professors and another M.D., and have shown, by certain certificates, that their medical studies have been pursued regularly.

The manner of conducting the examinations is chiefly by requiring written answers—a system which I need not defend, as it has been adopted from Cambridge by all the Universities, Colleges, and schools in England. The candidate for the degree of M.D. is also examined at the bed-side of the patient, and has there to prove his practical knowledge and skill in diagnosis and treatment.

In the examination for M.B., the number of those who fail in obtaining the degree is about one in five or six.

This letter has run to a much greater length than I intended. My excuse must be the *number* of errors to be corrected.

I will now conclude, in the very words in which your Correspondent himself began:—"It is a pity that he did not learn something more accurately about the British Universities, and understand his subject better before he sat down to make remarks."

I have the honour to be, Sir,
Your faithful servant,

July 26, 1849. M. D. CANTAB.

ANNIVERSARY OF THE PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

The Seventeenth Anniversary Meeting of the Provincial, Medical, and Surgical Association has just been held, under circumstances of peculiar interest. After having made a tour of some of the principal cities in the Kingdom, it once more returned to the place of its birth and to the Presidentship of its founder. The attendance of Medical men however, was not so numerous as might have been expected.

George Norman, Esq., F.R.C.S., Bath, President of the Association for the past year, took the chair, and proceeded to address the meeting. He said, the only duty which now remained for him to perform was, to thank them all for the kind attention shown to himself throughout his year of office. He must also express his satisfaction at his meeting the Association this year in the city of its birth, and that it was to be presided over by the gentleman to whom it owed its origin. (Great cheering.) It could not be hoped that all of them would live to see another seventeen years of the Association's existence, but he had no doubt that it would exist so long, and acquire all the strength and importance which its first founder had upon rational and fair grounds expected. He trusted, that after the lapse of another seventeen years, the Association would still find its founder capable of presiding over its meetings. (Loud cheering.) He had, in conclusion, only again to thank them personally for their kind attentions during the time he held the office of President, and to wish them all success, health, and happiness. (Much applause.)

Mr. Norman then gave up the Presidential chair to Dr. Hastings, who, on rising to address the meeting, was greeted with long-continued applause. We merely allude to his excellent and eloquent address, which, though long, was listened to with the greatest attention, and frequently interrupted by the applause of the meeting; neither do we give at length the "Report" read by Mr. J. P. Sheppard, since both will be published, and with accuracy, in the "Transactions of the Society."

Dr. Hastings congratulated the meeting not only upon the many eminent men who were members of the Association, but who had honoured them that day with their presence. When he compared the comparatively small body who had met seventeen years ago with the numerous band of physicians and surgeons,—zealous and successful cultivators of science, and occupying the highest places in the Profession,—who were now members of the Association, he felt that the glowing anticipations he had then formed had now been fully realised. He anticipated the most pleasing results and great scientific and social benefits from the happy annual meetings of the Association—eye beaming on eye, and voice answering to voice. He welcomed the members to the ancient and highly interesting city of Worcester, where, he assured them, they would be received with all those honours so justly their due. The Association had been the means of investigating and throwing much light on many important medical subjects; it had published the results of its inquiries, and had contributed greatly to the advancement and spread of knowledge. The great question of medical legislation had not been neglected, and the Association had contributed greatly to the cause of the Medical Charitable Institutions in the towns which it had visited. "In conclusion," said Dr. Hastings, "let me give expression to the great joy with which I hail this day, '*O diem lætum notandumque mihi candidissimo calculo,*' the day that this Association revisits Worcester, once the capital of an ancient kingdom; but still more closely linked to us as the centre of our flourishing Society. Let me also assure you, that in any thing which concerns the cause of science and the interests of humanity you may command my humble services; and that I highly value this Association, for I there witness the triumph of the social principle,—a principle I earnestly recommend you all to cherish; it is the principle which promotes peace; it is the principle of true honour; it is the principle of the Christian religion. (Long-continued applause.)"

The "Report" was then read by Mr. Sheppard, secretary *pro tem.*, who congratulated the members on again meeting at Worcester, where seventeen years ago the Society was first formed. Since that time the Association had spread its branches over every part of England, and members were connected with it not only in most of the European, but also in the American States; it was gratifying to reflect, that from the institution of this Society to this time, it had steadily advanced in importance, in influence, and usefulness. On each recurring anniversary there had been abundant cause for concluding that much benefit had resulted from the steady pursuit of the objects for which the Society was formed; and the Council were of opinion, that past experience had shown that its original constitution was a good one, and fully answered the purposes it was intended to serve. The death of Dr. Streeter had been deeply regretted; it would be long before his place could be adequately supplied; the Worcester Council had not failed to record their sense of his merit, and the loss the Association had sustained. The affairs of the Association were prosperous. At the present time, in return for an annual subscription of one guinea, every associate received once a fortnight a copy of the *Provincial Journal*, and since the last anniversary meeting, Parts 1 and 2, making the sixteenth volume of the "Transactions," have been published, and a copy been sent to every member whose subscription is paid. These great advantages could only be continued by a punctual payment of the subscriptions, which every member would feel called upon as his duty to do. The Council recommended, however, that the numbers of copies of the *Journal*, and of the "Transactions," to be printed, be regulated by the members who pay, rather than by the number of members who may be on the list. By these means the Council considered that a saving would arise on the expenses of the publications. The Report slightly alluded to the great questions of Medical Reform, Parochial Medical Relief, and the Benevolent Fund; recommended that Mr. Sheppard should be confirmed in the Secretaryship, and a new Editor appointed for the *Journal*.

Dr. Burrows moved—"That the Report now read be adopted and printed," to which he said he should wish to add, that the admirable address which they had just heard from their esteemed President should also be printed and put into circulation amongst the members. He could not say, that the address was an unexpected pleasure to him; for, from his long acquaintance with Dr. Hastings, he was prepared to hear from him those noble sentiments and the expression of benevolent feelings which he had known to be the inmates of that gentleman's breast. (Cheers.)

Dr. Little seconded the resolution, which, when put from the chair, was unanimously carried.

Dr. Conolly, of Hanwell, proposed the election of James P. Sheppard, Esq., to the office of Secretary, as recommended by the Council in their Report.

Dr. Forbes, of London, seconded the resolution, which was carried with applause.

Mr. Sheppard thanked the meeting for the compliment they had paid to him. He must call attention to the large number of members, that were in arrear with their subscriptions. He required that the publication of the Society should not be supplied to any such. There was now 1,828*l.* owing to the Society, and that without taking into account any

arrears below three guineas in amount. Under these circumstances he had a work of labour before him; but, if supported, he would unflinchingly do his duty. (Cheers.)

Mr. Flower, of Chilcompton, then moved, and Dr. Heygate, of Derby, seconded, a proposition, that Mr. Bartram, of Bath, and Mr. Martin, of Reigate, should be appointed auditors for the ensuing year.

Mr. Soden, of Sudbury, next very eloquently proposed, and Dr. Robertson, of Northampton, ably seconded, a vote of thanks to G. Norman, Esq., for his conduct as President during the year just past.

Mr. Norman could not allow the vote they had just passed to go by in silence, or without thanking them in return most cordially and from his heart. The private and friendly feelings of Mr. Soden had led him to rate his worth at a much higher value than the public had any right to do—(no, no)—but he felt very much all that he had said, and was deeply sensible of the kindness which had been shown to him by his professional brethren.

Dr. Conolly, of Cheltenham, proposed a Committee to consider the qualifications of the candidates for the editorship of the *Journal*, to report to the Council their decision within three months, and their choice to be subject to the confirmation or rejection of the general meeting in 1850.

Mr. Pierpoint, of Worcester, seconded the motion. Some discussion ensued, in which great stress was laid upon the necessity that existed of engaging thoroughly qualified man as Editor of their *Journal*, but ultimately the amendment, being put to the meeting, was lost, and the motion carried in its original form.

Mr. Crompton, of Manchester, brought forward the subject of the printing and publishing of the *Journal*. He said he had heard a great many complaints as to the general management and appearance of that periodical. One gentleman had observed to him that it was badly printed, bad ink, bad paper, badly edited, and badly folded; and he (Mr. Crompton) proposed that a Committee should be appointed to investigate its management, to see if it could not be more economically conducted, and to report whether or no the *Journal* should continue to be published in Worcester.

Mr. Greenhill seconded the proposal, and spoke strongly as to the cost of the *Journal* at present. A rather earnest discussion ensued, several gentlemen objecting to the remarks of Mr. Crompton, especially as to the paper being badly edited. Many members spoke of the gentlemanly tone of the leading articles and the total absence of all asperity. The President said, the Council had constantly in view the reduction of the expense of the publication of the *Journal*; and the proposition being put to the meeting, it was negatived by a large majority.

Mr. Flint, of Stockton, proposed, that the Council should be requested to issue a series of questions relating to cholera, which was unanimously carried.

A matter of a personal nature was next brought before the meeting by the President. A Mr. Edwards, of Wiveliscombe, was struck off the list of members of the Association, at the request of the West Somerset Branch, because he continued to hold consultations with a Mr. Blake, of Taunton, who had been excluded from the College of Surgeons. A vote of thanks was also passed to the West Somerset Branch, for following up the matter with such decision, and so strenuously upholding the honour of the Profession.

The Secretary then read a statement of the finances of the Association, which showed the receipts for the last year to be 1,718*l*., while the expenditure was within 16*l*. of that sum.

This concluded the business part of the meeting, and papers and cases were then read.

A case of successful Cæsarean operation was communicated by Dr. Radford, of Manchester; Mr. Crompton, Manchester, read a paper on burns and scalds; and Mr. Kitsell, of Droitwich, a short case of hydrocephalus, in which he had punctured the head of a little child some twelve months old in a case of decided hydrocephalus, took from it nine or ten ounces of liquor, and kept the puncture open by probings, instead of closing the wound, as usual in these cases. The result was a decided cure, and the infant, which was shown to the members on Thursday, appeared in good health.

The members adjourned about half-past five o'clock.

EVENING SITTING.

The members met again at eight o'clock, when Mr. Newnham, of Farnham, the Secretary to the Benevolent Fund, read the Report. He showed that both the receipts and the amount of aid enabled to be given had been doubled during the last year. Thirty-four cases of misery and destitution had been relieved, and the donation-fund had been increased from 1,183*l*. to 1,550*l*. The general subscription-fund had reached 510*l*. 7s. 10d., and the amount expended in relief was 454*l*.

Several gentlemen, including Dr. Cowan, Dr. Conolly, and Mr. Newnham, spoke on the subject; the whole meeting seeming to be deeply interested by the appeals and statements that had been made, and the conversation was only stopped by the President announcing, that the friends of the Benevolent Fund were to meet on the morrow morning, at eleven o'clock, and any suggestions might then be entertained.

The President then called on Dr. Sibson, of London, late of Nottingham, to deliver the address in Physiology.

The subject which Dr. Sibson chose for his remarks was, "The Physical Causes which excite the Respiratory Movements;" and his observations applied principally to those animals breathing with lungs. It must be kept in mind, that there are two distinct processes always going on with reference to the action of the respiratory organs, namely, the absorption of atmospheric air into the blood, and the elimination of carbonic acid by the blood, each of which was alike necessary for the continuance of life. Under different circumstances respiration went on with various degrees of vigour. He had used an instrument for the inhalation of chloroform to test this. There was a bladder attached to it which would contain 600 cubic feet of air. This he found he filled when at rest by twenty-two ordinary expirations—time about a minute and a half. In walking it was filled at about eleven expirations; and, after running as fast as possible, at four and five expirations. But it was not only by bodily exertion that respiration was influenced. The emotions of the mind had great influence upon it; under great depression of spirits it often almost entirely ceased, while a man in a great rage had a great deal of respiratory work to do. It was, therefore, of great importance to the medical practitioner to study the physiological causes of inspiration. The first inspiration in an infant was undoubtedly caused by the excitement of the air upon the surface of the body, and the discovery of the excito-motor nerves was one of the great triumphs of modern physiology. The knowledge of this cause of respiration was of great use to the medical man. In cases of poisoning by opium, for instance, the application of various stimulants to the surface—such as dashing cold water in the face, the application of heat to the feet, ammonia to the nostrils, electro-magnetism (not to the centres of the nervous system, but the nerves upon the surface)—might all be used in turn—as soon as one failed, to continue to produce respiration by another being applied till the patient was roused and recovered. With regard to the par vagum, though undoubtedly necessary to respiration, he did not consider it one of its causes; and the brain might likewise be removed, and yet the respiratory movements be continued. The arterial blood, but not the venous, when brought into contact with a larger portion of the surface of the body, was also one cause of respiration; and the knowledge of this fact might be of great use in cases of chronic asphyxia, as any means by which the action of the arteries could be excited might be a means of saving the patient.

Dr. Sibson's address was most pleasingly delivered, and very enthusiastically received.

Mr. Toynbee read a short notice on osseous tumors of the auditory passages, which elicited his opinion of the inutility of Mr. Yearsley's new medicine for deafness—glycerine. He had made 1,200 dissections of diseased ears, and believed that organ to be the subject of a greater variety of diseases than any other in the human body. In most of these, glycerine, or any other lubricating application, could be of no service. The dryness of the tube was only a symptom of the existence of other organic diseases—it was not in itself a cause of deafness.

The evening was concluded by Dr. Malden's reading a most able and highly-interesting paper on dreams, pointing out how they might in some cases indicate the presence of disease.

The sitting did not close till twenty minutes to twelve o'clock.

THURSDAY.

At half-past eight o'clock this morning, more than a hundred gentlemen breakfasted together in the large hall of the County Courts, and Dr. Hastings announced that the Infirmary was ready for inspection, and that the Dean and Chapter had thrown open the Cathedral to the Association; from the top of the tower of that building the best panorama of the city could be obtained, and his son, Mr. George Hastings, would accompany any who were interested in antiquities to point out the site of the battle-field of Worcester.

At the morning sitting at twelve o'clock, a Committee was appointed to confer with the London Committee now sitting, for the purpose of erecting a monument to Dr. Jenner.

The address in medicine was delivered by Dr. Bell, of Manchester, chiefly on "The Causes of the Production and Propagation of Disease." His observations were, for the most part, directed to strictures on the statements of the Board of Health, that quarantine was entirely useless, and that typhus, influenza, cholera, yellow fever, and plague all obeyed the same laws, and were only epidemically spread, and not diffused by contagion. Dr. Bell also considered the means by which poisons were propagated, concluding that all specific poisons were propagated by contagion, and that epidemic influence upon such diseases was only to give a peculiar character to them, and to make general their more particular operation upon one or other of the bodily organs. Typhus, scarlatina, and measles, therefore, were not epidemic, and ought not to have been classed by the Board of Health with cholera, yellow fever, and plague. Quarantine, therefore, was of use with regard to the first-named contagious disease, and a rigorous system of quarantine might have saved thousands of lives which had been sacrificed by the introduction of typhus by Irish emigrants. The only ground upon which the Board might have argued the propriety of abolishing quarantine as to these diseases was the presence of the virus already in the country. As to cholera, &c., which was really an epidemic disease, quarantine might be advantageously abolished. He hoped that the Medical Profession might become more united upon the subject of contagion,—as he thought they easily might,—and so a great cause of discredit with the public be avoided.

The usual thanks having been voted to Dr. Bell for his address,

Mr. Lord, a Deputation from the Convention in London for protecting the interests of the Poor-law Medical Staffs throughout the country, read a resolution of thanks passed by the Committee to the Association for the interest taken in the subject at its last year's meeting, and urged the necessity of strenuously taking up the subject of the payment of Poor-law Medical Officers.

Dr. Cowan (Reading) moved the adoption of a Memorial to the Poor-law Board, and a Petition to Parliament on this subject, which was seconded by Mr. Cantrell, of Wirksworth, and carried *nem. con.*

Dr. Sibson then proposed a Petition to Parliament on secret poisoning, upon the plan proposed by Dr. Toogood, of restraining the use of arsenic, by obliging druggists to have a special license for its sale, and by keeping a book in which the purchaser and a witness should be compelled to sign their names.

Dr. Tunstall (Bath) objected that the trouble it would entail upon the druggists would ensure their hostility to it, and the plan would not be feasible. It had been suggested to him, that if druggists were prevented from selling arsenic uncombined, the object would be accomplished. If all rat-powders were mixed with lamp-black and grease, it could not be put into human food without at once being discovered.

The subject was referred to a Committee of three gentlemen.

On the proposal of Mr. Martin, of Reigate, the next anniversary meeting of the Society will be held at Hull; F. R. Horner, Esq., M.D., of Bath, being nominated as President elect.

Cases having been read by Mr. Niven, of Pershore; Dr. Paxton, of Rugby; and Mr. Hare, of London,

Dr. J. Conolly reported the progress of a Committee appointed to consider the best method of bringing the subject of medical ethics under the attention of the members of the Association.

On the motion of Dr. Burrows, seconded by Mr. Paget, of Leicester, thanks were voted to the Mayor, Magistrates, and citizens of Worcester, for the kindness and liberality with which they had received the Association, to Sir J. Pakington and the County Magistrates, for the use of the Shire-hall, and to the Council of the Natural History Society for the use of the room.

The President then vacated the chair, which was immediately taken by Mr. Pierpoint.

Mr. Soden moved a vote of thanks to Dr. Hastings for his able conduct in presiding over the meetings of the Society. This was seconded by Mr. Newnham, both gentlemen expressing themselves as to the obligations which the Society was, and always had been, under to Dr. Hastings.

The vote was carried by acclamation, the whole

company rising from their seats and applauding for several moments.

Dr. Hastings returned thanks, and the meeting separated.

About 160 members and their friends dined together in the Assembly-room of the Guild-hall; and thus ended another anniversary of the Provincial Medical, and Surgical Association,—one which, according to the testimony of all concerned, yielded to none of its predecessors as regards the general instruction and pleasure it afforded.

MEDICAL NEWS.

Apothecaries' Hall.—Names of gentlemen who passed their examination in the Science and Practice of Medicine, and received certificates to practise, on Thursday August 2nd, 1849:—Thomas William Shea, England; John Syer Bristowe, England; Charles Morgan, England; Edmund Manley, Manchester; Walter Battershell Gill, London; Samuel Curtis Candler, Beccles, Suffolk; Frederick William Napoleon Wilson, Newcastle-upon-Tyne; George Garnham, Martham, Norfolk; James Fuller.

Royal College of Surgeons.—The following gentlemen, having undergone the necessary examinations for the diploma, were admitted members of the College at the meeting of the Court of Examiners on the 3rd inst.:—Messrs. Thomas Hardy, London; Edmund Manley, Manchester; Charles George Woodd, Bromley, Kent; Edward Morgan Puddicombe, Dartmouth, Devon; Algernon Sudlow, Twickenham, Middlesex; Benjamin Davies, Froodvale, Carmarthenshire; John Candler, Aylesworth, Suffolk; Thomas Hutchinson, Camborne Cornwall; Richard Pope Jeston, Henley-on-Thames; James Gilbert Martyn, Camelford, Cornwall; James Rigby, Stockport, Cheshire; and John Clarke, Newbury, Berkshire; at the same meeting of the Court, Mr. George Edward Nicholas passed his examination for Naval Surgeon; this gentleman had previously been admitted a member of the College, his diploma bearing date February 6, 1846. And on the 6th, Messrs. David John Whitty, Aberdare, Glamorganshire; Thomas Bryant, Clapham-road; Frederic Duke, Hastings, Sussex; Isaac Tucker, Westbury Leigh, Wiltshire; and George Johnstone, New York.

The College Council.—There are two more vacancies in the governing body of the Royal College of Surgeons, which was so recently filled up, viz., by the death of Mr. Goldwyer Andrews, and the resignation of Mr. R. Welbank.

Fellowship of the Royal College of Surgeons.—We understand that ten gentlemen presented themselves as candidates for the Fellowship of the Royal College of Surgeons, whose names we shall next week publish. The following questions were proposed to the candidates on Tuesday and Thursday last, viz.:—Anatomy and Physiology. Senior Candidates. First Day. 1. Describe the regions into which the abdomen is divided, and the situation of the viscera in those regions. 2. Describe the course of the large intestine from its commencement to its termination, with its connexions of peritoneum. 3. Describe the vena portæ, namely:—The veins which form it, and the sources from which they are derived; the course and relations of its trunk; the distribution and termination of the branches from the trunk; and the vessels which convey the blood from the liver. Also, the differences of the portal circulation in the fœtus. 4. Describe the structure of the shoulder-joint, with the situation and actions of the muscles which move the os humeri. 5. Describe the nerves which supply the globe and muscles of the eye. 6. What are the proofs that the blood circulates? The following were submitted to the Junior Candidates:—1. Describe the structure of the larynx, namely, its cartilages, joints, ligaments, muscles, vessels, nerves, and lining membrane; also the mode in which a vocal intonation is produced and modulated. 2. Describe the structure of the iris, with its vessels and nerves, and the functions of the iris in connexion with vision; explain also the influence of the nerves on the varying size of the pupil. 3. Describe the causes and conditions of the buffy coat of the coagulum of the blood, and the various circumstances which modify its formation. 4. Describe the structure and functions of the trunks and larger branches of arteries, and also the disposition, structure, and functions of the capillary vessels. 5. Describe the origin, connexion, course, and distribution of the fifth cerebral nerves, and their functions, both generally and in the several parts which they supply and state in what respect, if any, they are analogous to spinal nerves. 6. What information does the microscope afford with respect to the structure, origin, and termination of nerves. The following were the questions proposed to the senior candidates on the second day (Thursday) in Surgery, viz.:—1. Describe the process by which fractured bones are united through its several stages. 2. What is the state of the blood-vessels, and of the blood circulating in them, in any part affected with phlegmonous inflammation; and what are the changes which take place in the inflamed part? 3. What are the effects and remedial uses of mercury, when so administered as to affect the system? What are the signs of the injurious influence of the remedy under a protracted course? And how should it be administered in order to obtain its full influence on the system? 4. What are morbid changes which have been discovered in the *post-mortem* examination of persons who have died of tetanus? What light has been thrown on the causes of the disease, either by morbid anatomy or experiments on the lower animals? And what is the state of our knowledge of its pathology? 5. Describe the operations of laryngotomy and tracheotomy; and state the difficulties and dangers which belong to these operations. 6. What is the nature of cancerous or malignant disease? What are its forms? What is the anatomical character of each? What is its mode of propagation? And what are the organs which are primarily or secondarily affected?

Obituary.—At an advanced age, W. M. Thackeray, Esq., M.D., senior Medical Practitioner at Chester.

The late Mr. Clift.—The sale of the effects of this gentleman took place last Friday and Saturday. The books, which were generally in good condition, realised but indifferent prices. They were remarkable from the great number of curious notes they contained, in the handwriting of the deceased, having reference to the eventful period in which he lived, and contained his opinion of men and manners,—and valuable notes many of them are. The principal purchasers were Mr. T. M. Stone, of the College of Surgeons, and Mr. Guerrier, the builder of the same Institution. One of the lots, a Medical Journal in excellent binding, excited some amusement from its being lettered "*The Stiletto,*" instead of the correct title; the cause assigned for this eccentricity being, in the opinion of its owner, the freedom with which "*it stabbed people in the dark.*" In the second day's sale of furniture, there were a few lots deserving of notice, viz., the looking-glass of John Hunter, knocked down to Mr. Quekett; and the mahogany book-case and writing-desk, which Mr. Stone was so fortunate as to secure, together with Sharp's line engraving of Hunter, one of the earliest proofs of this great work of art, and a brilliant impression of the scarce print of Abernethy, both of which had been presented to Mr. Clift by the parties themselves. Mr. Stone also obtained several valuable medical portraits and autographs.

The Cholera.—The Reports during the past week, from the provinces, show that this disease, upon the whole, has a tendency to decline. In some large towns the cases have been numerous, but there has been a diminished mortality. In Gloucester and Worcester it has disappeared, and those, with many other towns, will probably remember the visitation, as much for the sanitary reform which it has brought about as for the fatality which has attended its progress. In the American Union cholera has been advancing with fearful rapidity. New York has been panic stricken by the number of deaths which have occurred amongst all classes from it, and the authorities there are using all the efforts which science and humanity can suggest to arrest its progress. No successful mode of treatment has yet been published. We subjoin the weekly Report of the Registrar-General for this metropolis:—It is unsatisfactory to observe, that the constant increase of mortality, which commenced in the second week of July, was maintained in the week ending Saturday last. The deaths from all diseases in last week were 1967—a mortality nearly double the weekly average of the season, which is 1008. The progress of the mortality is shown by the following numbers returned in the last four weeks:—1369, 1741, 1931, and 1971. The deaths from cholera, which in six previous weeks were 49, 124, 152, 339, 678, 783, increased in the last to 926. A feature worthy of notice in the present return is the fact, that, while the mortality caused by cholera has increased, there has been simultaneously a decrease in the deaths attributed to diarrhœa; for whereas the deaths from this disease (including dysentery) were in four previous weeks 54, 100, 146, 239, in the last week they declined to 198, an amount which is nearly the same as in the corresponding week of the summer of 1846, and little more than that of the same week of 1848. It is shown, therefore, that the total mortality from diarrhœa, dysentery, and cholera amounts in this return to 1,124, while the average is only 92. Consequently the excess from the three epidemics exceeds in some degree the increase above the average of the mortality from all causes, which is owing partly to the circumstance that the death from fractures, burns, and other injury registered in the week were unusually few. Other epidemics besides those mentioned are under the average, with the exception of hooping-cough, which a little exceeds it. The mortality from cholera still predominates on the south side of the river, the deaths there, which in the preceeding week were 514, rose in the last to 621. On the north side of the Thames the deaths in the western districts were 31, showing an increase; in the northern 27, or nearly the same as in the former week; in the eastern 127, a slight increase; and in the central, which includes St. Giles and St. George, Strand, Holborn, Clerkenwell, St. Luke, East London, West London, and City, there is a small decrease, the number being 93, though in the previous return there were 97 deaths. The greatest number in any district on the north side of the river is in West London, namely, 32. Of the southern districts, there were 67 in Bermondsey, 86 in Newington, 112 in St. George, Southwark, and 143 in Lambeth. The deaths in Rotherhithe are now comparatively few. The death of a man of 40 years in Brompton was caused by erysipelas of both legs, of putrid character, (after five days' illness,) caught from sleeping with a child who suffered from the disease. The daily mean of the barometer was highest on Thursday, when it was 29.965. The mean of the week was 29.793. The temperature was under the average of the corresponding days of seven years on every day except Thursday. The highest in the shade was on Thursday, namely, 74°·5. The mean temperature of the week was 59°·5

The General Board of Health.—The new Act for confirming certain provincial orders of the General Board of Health, and for other matters relative to the Public Health Act and the improvement of towns and populous places (12th and 13th of Victoria, c. xciv.), will speedily be enforced. Provisional orders relating to Taunton, Worcester, Ware, Sheerness, Kendal, Durham, Leicester, Chatham, New Windsor, Carmarthen, Glocester, Lancaster, Croydon, Uxbridge, and Coventry, are confirmed. Elections for Local Boards of Health are appointed to take place in the course of the present month. By the 8th section Local Boards of Health, constituted under the Public Health Act, are authorized to contract, for any period not exceeding three years at any one time, with any company or person for the supply of gas or oil, or other means of lighting the streets, roads, and other places of their respective districts, and may provide lamps and other materials, and the expenses shall be defrayed out of the general or special district rates levied under the said Public Health Act. This Act is to be incorporated with the Public Health Act, 1848, and to be called "The Public Health Supplemental Act, 1849."

Society for Relief of Widows and Orphans of Medical Men in London and its Vicinity.—At the last Quarterly Court of Directors of this Society, it appeared from the Report of the Acting Treasurer, Dr. William Merriman, that during the last financial half year, ending on the 20th May, 1849, the following donations had been received, principally at the annual dinner on the [illegible] of April, viz:—H. R. H. the Duchess of Gloucester, 10*l.*; the Society of Apothecaries, 15*l.* 15s.; Sir Charles M. Clarke, Bart., (the President;) Sir Richard Sutton, Bart.; H. Tudor, Esq.; R. Stephenson, Esq.; Dr. Richard Bright; William Pennington, Esq.; Thomas A. Stone, Esq.; Dr. Alexander J. Sutherland, each 10*l.*; the British Medical Association, 10*l.*; Mrs. Tudor; J. T., by Dr. Lever; Dr. Joseph Arnould; Dr. Leman; John Hunter, Esq., (late Acting-Treasurer;) Thos. F. Chilver, Esq.; T. Reynolds Jackson, Esq.; John Propert, Esq.; each 5*l.* 5s.: Sir James M'Grigor, Bart.; William Hunter Baillie, Esq.; Martin Ware, Esq.; each 5*l.*: Rev. Charles Clarke, Dr. Conolly; Dr. Locock; R. Blagden, Esq.; W. S. Burton, Esq.; J. E. Sanderson, Esq.; H. P. Fuller, Esq.; Thomas Hammerton, Esq.; George Beaman, Esq.; James York, Esq.; each 2*l.* 2s.: Rev. S. Wix; Rev. H. Penny; Bransby B. Cooper, Esq.; E. A. Lloyd, Esq.; Charles Law, Esq.; Miss Merriman, Edmund C. Johnson, Esq.; L. Freeman, Esq.; R. Stocker, Esq.; G. J. Squibb, Esq.; John Clarke, Esq.; Charles Alexander, Esq.; Dr. Theophilus Thompson; each 1*l.* 1s.

The Judges and the Medical Profession.—At the close of the Haltwhistle trial, on Wednesday, the Judges of Assize made an order for payment of a fee of twenty guineas to Dr. Glover, the principal medical witness, being the highest amount which it was in their power to award.

MORTALITY TABLE,

(Metropolis.)

For the Week ending Saturday, Aug. 4, 1849.

Causes of Death.	Total	Average of Five Summers
All Causes	1967	1008
Specified Causes	1963	1005
Zymotic (or Epidemic, Endemic, and Contagious) Diseases	1308	302
Sporadic Diseases		
Dropsy, Cancer and other Diseases of uncertain or variable seat	41	44
Tubercular Diseases	164	190
Diseases of the brain, Spinal Marrow, Nerves, and Senses	110	119
Diseases of the Heart and Blood vessels	50	29
Diseases of the Lungs, and of the other Organs of Respiration	85	81
Diseases of the Stomach, Liver, and other Organs of Digestion	64	76
Diseases of the Kidneys, &c	11	11
Childbirth, Diseases of the Uterus, &c	3	7
Rheumatism, Diseases of the Bones, Joints, &c	5	7
Diseases of the Skin, Cellular Tissue, &c.	1	2
Malformations	1	8
Premature Birth and Debility	30	22
Atrophy	18	25
Age	87	43
Sudden	12	8
Violence, Privation, Cold, and Intemperance	23	36
Causes not Specified	4	3

The following is the number of Deaths occurring from some of the more important special causes —

Apoplexy	26	Heart	15	Phthisis	112
Bronchitis ...	30	Hooping cough	33	Pneumonia ...	44
Cholera.........	926	Hydrocephalus	26	Scarlatina . ..	44
Childbirth	1	Influenza	..	Small-pox	11

HUNTERIAN LECTURES

ON THE

GENERATION AND DEVELOPMENT OF THE INVERTEBRATED ANIMALS.

By RICHARD OWEN, F.R.S.,

Hunterian Professor and Curator of the Museum of Royal College of Surgeons, Corresponding Member of the Institute of France, &c.

[Reported expressly for the "Medical Times," and revised by the Lecturer.]

LECTURE XI.

GENERATION OF EPIZOA AND CIRRIPEDIA.—General characters of these parasitic Articulata.—Arrested development of the dwarf-males of Epizoa.—Male organs of Achtheres.—Complex female organs of Epizoa. the external ovisacs.—Development of embryo and retrograde metamorphosis of the young into the adult animal.—Organs of generation of the Cirripedia conflicting opinions respecting them: they are androgynous.—Dendritic testes: glandular sperm-ducts and long proboscidiform penis.—Ovaria, their different position in sessile and pedunculate Cirripeds. extreme metamorphosis in this class.

MR. PRESIDENT AND GENTLEMEN,—The phenomena of the generation and development of the animal kingdom, so far as we have traced them, must, already, have impressed us with the inadequacy of the knowledge of the nature of an animal in its final and complete stage of existence only, for the determination of its affinities and proper place in the scheme of Nature. This fact was demonstrated with regard to many of the previous objects of our study: it is still more obvious in respect of the class of animals which will occupy our attention to day. I may also here observe, that whilst it is essential to trace the metamorphoses of each species in order to rightly comprehend its true nature, the study of the generative organs shows that we cannot rely on them alone for a system of classification. We saw, for example, that some of the anellides combined both male and female organs in the same individual, while others had those organs separate and peculiar to distinct individuals; one order was androgynous, another diœcious. In the earth worm we had evidence of a certain concentration of the generative system within a few segments, and in the leech, of their more general diffusion and subdivision; but this vegetative character was most remarkable in the diœcious annellides, in which almost every joint presents either its pair of testes or of ovaria, according to the sex of the individual. Then, in reference to the progress of development of these worms, some transitorily manifested the form and character of one class, inferior to them in the animal scale, and others those of another lower class; thus, the embryo leech represented the planaria, whilst most of the higher annellides come forth from the ovum more like infusorial animalcula. The further progress of development was interesting, since it reminded us of that singular propagation of certain Acalephæ, in which the larva produced other larvæ like itself, before it was metamorphosed into the final form of a medusa. For the ordinary mode of growth of the Annellide, by the development of joint after joint, one precisely similar to the other, throughout a series of, perhaps, hundreds of joints, with only the first and the final segments distinguished by any peculiar characteristics,—all this process of growth looked very like an incomplete parthenogenesis; but this mode of production is fully manifested by the successive casting off of groups of segments, with the characteristic head and tail, as in the instances of gemmation of the naids and nereids last described; the young annellide from the ovum propagating at first by gemmation and spontaneous fission; and the individuals so produced developing the ordinary organs of generation.

The low organized articulated classes, which succeed the annelides in the progress upwards, undergo such extraordinary metamorphoses before attaining their mature state, as to mask their true relations, not only to the class, but to the primary division of animals to which they belong. This is especially the case with the creatures whose organization and development will form the subject of the present lecture.

This elongated, cylindrical, unarticulated Lernæa, (showing the preparation,) whose smooth soft body seems devoid of any other appendages than the two long slender ovisacs, might be regarded as one of the Entozoa of the fish to which it is attached, and on the nutrient juices of which it subsists.

This barnacle, imprisoned in its conical calcareous shell, and cemented to the stone on which it grew, might seem as naturally to belong, like its neighbour the limpet, to the testaceous Mollusca.

How minute and accurate must have been the investigation of the forms and structures of these animals, at every stage of their existence, before the truth could be discerned, that they were more nearly allied to one another than to any other class of animals! The most vivid imagination of the boldest generaliser or speculator upon the unity of organisation in the Animal Kingdom could never have divined that the Lernæa and the Cirripede were at one period of their lives locomotive animals, swimming about under very similar forms, and by almost identical natatory instruments,—not under the common ciliated infusorial form, in which the young of certain Entozoa and Mollusca first enter into active life; but with symmetrical pairs of jointed setigerous legs like those of the Annellides and the lower organised Crustaceans, to which the *Epizoa* and *Cirripedia* are, in fact, essentially and most closely allied, although they end their career as sedentary animals under such different, such diversified, and, as regards the Epizoa, such grotesque forms.

These metamorphoses lead to very different results from those of the Medusa and Comatula. The Epizoa and Cirripedes acquire increase of bulk and organs of generation; but, in every other respect, the varied course of their development ends in a retrograde movement. Their development would seem to have been at first, as it were, hurried forward at too rapid a pace, and the young parasite, starting briskly into life, ranging to and fro by the highest developed natatory organs we have yet met with, and guiding its course by visual organs, must lose its eyes and limbs before it can fulfil the destined purpose of its creation.

The *Epizoa*, by which name we recognise the singular class of animals which infest the skin, the eyes, and the gills of fishes and other marine animals,—these external parasites, which are as numerous as, and perhaps more numerous than, the whole class of fishes,—are distinguished in their mature state by a body of a more or less elongated or sub-cylindrical form, defended by a smooth, semi-transparent, parchment like integument, having a more or less distinct head, and generally a pair of long cylindrical ovisacs, dependent from the opposite extremity of the body.

In this low organized class of Articulate animals, as in the classes which commence all other great primary groups, there is an extensive gradation of forms by which we pass from species slightly elevated above the cavitary Entozoa to the true Crustaceans.

The lowest or most simple Epizoa adhere by a suctorious mouth, and traces of extremities exist only in the form of a few minute pairs of obtuse inarticulate processes. In the highest organised species, the adhesion is effected by jointed mandibles with terminal hooks or forceps. The head, in most of the species, is found, when closely examined, to present a pair of jointed antennæ, which, contemplated by the experienced naturalist, cognizant of the value of such characters, might excite the suspicion that relations to higher *Articulata* than the Anellides were hidden under the bloated form which indolent and gluttonous habits had superinduced upon the pendent parasite. Observation of it during its early and independent state has proved this to be actually the case to an extent which could scarcely have been anticipated.

The Epizoa are of distinct sexes: the male appears, always to retain his freedom, and is, perhaps on that account, singularly smaller than the female, generally not more than a fifth part of her size, consequently, for a long time, the males escaped recognition. They adhere to the vulva with one antenna usually inserted therein. The individuals of the productive sex, distinguished throughout a great part of the year by their pendent ovisacs, are the examples usually seen of this curious class; and in these I shall proceed to describe the anatomical characters of the Epizoa.

The body, independently of the ovisacs, is generally divided into two segments: the anterior and smaller division sometimes supports a distinct head, but more commonly corresponds with the cephalothorax of the Crustacea: the larger segment is called the abdomen, and in it the ovaria are developed. You will not unfrequently find adhering to the eye of the sprat an Episoon or Lernæa, which is a nearly allied species of the same genus (*Peniculus*), as the specimen figured and described by Nordmann, which infests the boar-fish (*Zeus aper*). In the *Peniculus fistula*, the head is oval, and notched anteriorly, each division being armed with an inwardly bent hook, or rudimental jaw. The mouth is immediately beneath these, in the form of a circular orifice, supported by a short cartilaginous tube. At the posterior contracted part of the head are two pairs of short, oval, flattened processes: a constriction or neck separates them from the thorax, at the commencement of which there is a third pair of similar rudiments of locomotive appendages. The thorax is round, and separated by a constriction from the abdomen, a fourth pair of appendages being developed from the interspace. The alimentary canal is much contracted in the neck and thorax, but expands in the abdomen into a moderately wide, and uniform intestine, which again slightly contracts to terminate by a distinct anus at the hinder extremity. The alimentary canal has the same simple straight course in other species of Epizoa. One cannot be surprised at this correspondence with its general condition in the cavitary Entozoa, when the similarity of their easily assimilable nutriment is remembered. The intestine, is, however, complicated in the Epizoa, with a conglomerate or minutely-lobed glandular mass, developed from nearly the whole extent of the abdominal tract of the intestine, and which may fulfil the function of a liver.

In some species which attach themselves to the gills and the like favourable positions for an abundant supply of the most nutritious fluid, the body is frequently deformed, as it were, by excessive growth, and cæcal productions from the simple straight intestine are continued into the prolongations of the thoracic or abdominal walls. The Nicothoe, a small parasite of the gills of the lobster, is an example of this condition of the digestive organ. The first segment of the body is produced into two lateral symmetrical wing-shaped lobes, each four times the length of the segment to which they are attached, and they contain corresponding cæcal prolongations of the straight intestine.

In the species of Lernæa exhibited (*Peniculus fistula*), the abdomen contains, in addition to the alimentary canal, two slender tubes, the ovaria and oviducts, commencing by blind extremities near the anterior part of the dilated intestine, and continuing with a slightly wavy course to terminate at the two apertures, to which the ovisacs are attached.

These ovisacs singularly resemble the seed-capsules of certain plants, especially the *cassia fistula*, being divided into a series of cells or chambers by transverse septa, placed at regular distances. Each cell contains an elliptical or lenticular ovum.

Two slender white filaments running almost parallel with, but at a distance from, each other, through the whole length of the under surface of the abdomen, nearer the margins than the middle line, form the chief and most conspicuous part of the nervous system.

The Epizoa differ from one another in their mode of adhering to the fish they infest. some stick fast by a suctorial mouth; others by processes that grow from the head; but the most common mechanism of adhesion in the Epizoa is a circular sucker developed upon the confluent extremities of a pair of obscurely jointed tubular feet, the third thoracic limbs of the larva,—as in this *Lernæopoda*, of the shark, (showing No. 280 A.) and, as in the *Achtheres* of the Perch, the *Tracheliastes* of the Chub, &c. In the last-named parasite, which may

be found adhering to the fins of the Chub in the months of October and November, the head and thorax are confluent, unless the segment to which the bases of the before-mentioned feet are attached be held to represent the thorax. The abdomen is as usual, the largest segment. The mouth is a circular aperture, fringed with minute short bristles on each side there is a maxilla dentated at the inner margin, and terminated by a bifid hook. The antennæ are represented by two short lancet-shaped processes, terminated at the apex by a few extremely short bristles. The most conspicuous appendages of the head are, however, a pair of mandibles, which consist of two obscure joints, the second of which has a bifid extremity; the outer division is armed by a strong curved spine, which is opposed to two short straight spines; the inner division is tipped with four small spines. Immediately behind the large tubular prehensile process is a short rudimental extremity, supporting a moveable hook which is opposed, as in the mandibles, by two short spines. The muscular system is sufficiently conspicuous in the head of this Epizoon in the form of distinct fasciculi of fine fibres.

In this *Penella* (showing No. 286) the head resembles a cauliflower, swelling out into a globose groupe of slightly branched and obtuse wart-like processes, which must have grown after the head had become imbedded in the flesh of the fish to which it is attached. Two long tubular processes or extremities are developed at the junction of the thorax with the abdomen; but their extremities are free, simple, slightly attenuated, and obtuse. On the under surface of the body, in the interspaces of these appendages, there are four pairs of simple, small, oval, flattened feet; their pointed extremities extend only half way to the sides of the part of the body to which they are attached. The body is prolonged beyond the ovisacs in the form of a tail, which is provided on each side with a series of sixteen slender cylindrical appendages, close set in an oblique position, like the barbs of a feather, or the vane of an arrow, whence the specific name *Sagitta*, given to this parasite. The caudal lamellæ of the higher Crustacea would seem to be here sketched out.

The anatomy of the Epizoa has been most elaborately traced out by Nordmann in the parasite of the common perch, called *Achtheres*. In this species two lateral teeth project from the circular mouth, the labial margin of which is fringed with bristles. Here, also, we have mandibles and maxillæ, the latter provided with palpi; and, besides these, a pair of jointed antennæ, each terminated by three setæ. Now, this is a very important external character; it is the first instance of true jointed antennæ that we have met with in our ascending survey, and the acute zoologist might be led to surmise, from their presence, that relations of higher affinity were masked beneath the general character of the vermiform body of the parasite, and we shall be able to raise the mask as we trace the metamorphoses of the species.

The circulating fluid consists of a clear plasma, with granular corpuscles of different forms and sizes. The pulsatile vasiform heart may be seen at the middle line of the cephalo-thorax propelling the blood, forwards by rythmical contractions. Two canals pass from it into the hollow prehensile feet. The rest of the blood is distributed to the head, and along each side of the commencement of the alimentary canal to the under part of the body, where it passes backwards in the vessel which accompanies the intestine.

The ovaria at first appear in the form of a slightly flexuous, long, blind tubes, sacculated along one side. As the ova are developed, the ovarium takes on the form of a bunch of grapes, and occupies the whole cavity of the abdomen external to the intestine: each ovarium terminates by a triangular, and somewhat prominent orifice, to which the external ovisac is appended.

The Epizoa are remarkable for the disproportionate size of the sexes. In the minute male, the testes are indicated by four dark coloured and finely granulated bodies situated in the posterior segment or abdomen. He appears like a mere parasite of the female to which he adheres, near the vulva, and having usually one antenna inserted into that aperture.

The first remarkable circumstance in the natural history of the aquatic Epizoa is the constancy with which particular species infest particular fishes or crustacea. And how, it may be asked, can creatures so devoid of means of transport, nay, in most instances, of the power of detaching themselves from the animals whence, like fœtuses, they derive their means of growth, originally reach the precise species of animal and organ to which they are habitually attached?

Are certain of the ova accidently retained near the parent after the rupture of the ovisac, and there grow, like seeds of plants fallen in a favourable soil Or, do some of the liberated ova, by a happy fortuity, arrive at the appropriate organ of the appropriate species, and are they there accidentally retained until the prehensile instruments are developed? Such hypotheses may be permitted in reference to the ova of an Entozoon which are developed by millions, and need only to be swallowed by the animal in whose intestine they are adapted to exist; but the ova are too few in the Epizoa, and the parts to which they are attached are too exposed, to allow of the supposition that their parasitic growth is dependent on such accidental circumstances.

MM. Audouin and Edwards appear to have been the first to suggest that the sedentary Lernæan Epizoa might enjoy at a previous period of existence locomotive powers, and the hypothesis was supported by the discovery, made by Dr. Surriray, of the embryo of a *Lernæocera*, still in the ovum, which, instead of resembling the parent, presented the characters of a locomotive Entomostracous monoculous Crustacean.

The singular metamorphosis thus indicated has been traced out and generalised by the careful observations of Dr. Nordmann. The following is the general course of development of the Lernæan parasite of the Perch.

The female Achtheres is devoid of ovigerous appendages in the months of December, January, and February. In March they are developed by the eversion of a membrane prepared in the ovarian sac. Each sac hangs by a short tubular peduncle which is in direct communication with the short oviduct. The outer membrane of the ovum or chorion is moderately thick and transparent; the inner membrane is thinner, and includes both the vitelline mass and albumen. The yoke forms the largest proportion of the contents of the ovum, and is finely granular. One of the first parts of the embryo discerned by Nordmann was the dark ocellus. A pair of cylindrical processes shoot out from each side of the fore part of the embryonic or vitelline mass; and a pencil of hairs is developed from the extremity of each process. The body slightly elongates; the exterior albuminous fluid increases, the inner membrane expands, and the outer one bursts and is shed. The movements of the imprisoned embryo increase in force until it bursts the remaining membrane of the ovum, and escapes from the ovigerous sac. It then presents the form represented in the diagram. The locomotive organs are [illegible] pairs, and consist of tubular processes of the tegument, including a fasciculus of bristles. You perceive that these locomotive organs present the type of the Annellida. And since we were led from the Infusoria to the Polypi, because the ciliated larvæ of these resembled the monads, and since we passed from the Polypi to the Acalephæ, because these in their larval state were polypes, so we have now the same indication from a transitory step in development for passing from the Annulata to the Epizoa, and for ranking these parasites on a higher step of articulate structure; and not with the Entozoa, where Cuvier and Lamarck left them.

In the course of half an hour the young *Achtheres* undergoes its second stage: the first integument is loosened by the formation of a second beneath it, which now incloses a body, altered in its shape and in the number and nature of its appendages.

The process of moulting lasts from eight to ten minutes. A great proportion of the original germ-mass remains unaltered, surrounding the simple intestine, and extending into the bases of the tubular feet of the larva. The *nisus formativus* proceeds to operate on this material, but on a modified plan. The second body, which is formed inside the husk of the first, now cast off, is divided into an anterior and a posterior segment, the latter consisting of four joints. A pair of four-articulate setigerous antennæ diverge from the anterior part of the body. Between the antennæ is the large single median eye, as in the monocular Entomostracous Crustacea. The little Epizoon is now provided with five pairs of feet, the first three pairs terminate by a simple hook; the last two pairs are bifurcated, one division being hooked and prehensile, the other tubular and emitting tufts of bristles; these natatory feet strike the water together, and propel the body forward with a jerk; they are aided by the last segment, which is terminated by four setigerous tubercles.

The antennæ probably serve to indicate to the young parasite its appropriate object, to which it then proceeds to attach itself. The first pair of feet is approximated towards the mouth, and forms the uncinated mandibles. The second pair of feet increases in size, and the terminal hook enlarges; they serve to seize and hold on to the surface of the fish selected. The feet of the third pair lengthen and unite together to form a cartilaginous circular sucker, and permanently anchor the parasite to its prey.

The two sexes are alike in their young and locomotive state: the male at its final metamorphosis retains the first pair of feet as mandibles, very similar in form to those of the female: the second pair is shorter and thicker: the legs of the third pair always remain separate from each other, and consists usually each of two large joints, the last one terminated by a claw. The posterior natatory feet disappear in both sexes; and, with the loss of these instruments of locomotion, the eyes, also, are blinded and absorbed.

Before proceeding to the *Cirripedia*, I would offer a few remarks on the real nature of the changes just described. They are commonly spoken of under the same name as that given to the changes of insects; and perhaps they differ only in degree. The metamorphosis in all insects is attended with the casting off of a certain proportion of the precedent individual, called the "moult," or the new animal may be said to creep out of the old, from which the process is called the "ecdysis." With regard to the so-called metamorphosis which issue in the succession of a fixed, blind, sessile multivalve barnacle to a free-swimming crustacean with pedunculated eyes, or in the succession of a rooted vermiform parasite to a natatory animal with articulated setigerous limbs. When these phenomena are closely traced, they are seen to depend in a greater degree upon the action and coalescence of retained cells, than upon a change of form of pre-existing tissues. If the development of the ovum in the pedunculate ovarian sac of the low crustaceous external parasite of a fish be closely traced, the peripheral cells of the germ-mass are seen to combine and coalesce to form the smooth transparent skin of the embryo Lernæa, from which also tubular processes extend in two (*Achtheres*) or three (*Lernæocera*) pairs, including setæ which project from their extremities.

In the *Lernæocera* the anterior pair is directed forward like antennæ, but they are unjointed; and the head is further indicated by a coloured eye-speck. Another layer of germ-cells have perished, as such, in order to form the parietes of a straight and simple intestine, with a mouth and anus. Thus the annelidous type is first manifested.

But a large proportion of the minute germ-cells remain in the wide abdominal interspace, amassed around the alimentary tube, and aggregated in groups at the base of the tubular and setigerous feet. With respect to the latter, we might say that the same provision is made for the reproduction of the limbs as is retained throughout life in regard to those of the lobster. In the larval Lernæa, however, those reserve-cells commence the formation of new limbs irrespective of any injury to the old ones. The whole peripheral stratum of the retained germ-mass,

in contact with the primary integument, is transformed into a new integument. These germ-cells have increased and propagated at the expense of the aliment assimilated by the alimentary canal. The formation of the new integument and of the new feet proceeds connectedly and contemporaneously; but the new parts are not moulded upon the inner surface of the old ones. The plastic force has changed its course of operation. A hinder segment of the body is added to the front one, which answers to the whole of the body of the first larva. If antennæ did not before exist, a jointed pair is now developed. Instead of two pairs of tubular setigerous limbs, three pairs of uncinated prehensile limbs are developed from the anterior or cephalothoracic segment, and as many pairs of articulated setigerous limbs from the abdominal segment. New muscles, new nerves, and new vessels are formed for the support and exercise of these various instruments. The outer case, and all that gave form and character to the precedent individual, perish and are cast off; they are not changed into the corresponding parts of the new individual. These are due to a new and distinct developmental process; rendered possible through the retention of a certain proportion of the unchanged germ cells. The process is essentially the same as that which developes the cercariform larva of the Distoma within the gregariniform one, or the external bud from the Hydra, or the internal bud from the Aphis. It is a slightly modified parthenogenesis; and the phases by which the locomotive annelidous larva of the Lernæa passes through the entomostracous stage before retrograding to the final condition of the oviparous, limbless, bloated, and rooted parasite, are much more those of a metagenesis than a metamorphosis.

I now proceed to the second class of Articulated animals, which I here groupe with the Epizoa.

Many of the *Cirripedia* are parasitic animals, like the *Epizoa*, but are dependent upon the organized bodies to which they are attached for their place of residence, not for their food; those species which do not infest other animals are attached to sea-weed, floating timber, or rocks. The Cirripedes are symmetrical animals, with a soft, inarticulated body enveloped in a membrane; they are provided with six pairs of rudimentary feet, obscurely divided into three joints, and terminated each by a pair of long and slender many-jointed, ciliated tentacles, curled towards the mouth, and thence giving origin to the name of the class. They are androgynous.

The mouth is, in most species, provided with a broad upper lip, with two palps or feelers, and three pairs of dentated and ciliated jaws. The opposite extremity of the body is prolonged into a slender, many-jointed, ciliated caudal appendage, which is traversed by the generative canal. The mouth is situated near the anterior extremity of the body, which is modified to form the organ of attachment of the animal. It is sometimes produced to a considerable extent, and is of contracted diameter, forming a long and flexible peduncle; sometimes it expands at once into a broad disc or basis of adhesion. The Cirripedes are divided according to these modes of attachment into two primary groups, viz., the pedunculated, or *Lepadoids*, and the sessile, or *Balanoids*. The first are commonly known by the name of Barnacles; the second by that of Crown-shells or Acorn-shells.

Most of the Cirripedes have their visceral cavity protected by a calcareous shell composed of many pieces; but in some, as the *Otion*, the membranous or pallial investment of the viscera is protected only by an elastic, horny sheath, continued from the epidermal covering of the peduncle. Two small calcareous bodies, developed in the substance of the outer envelope, just above the brachial fissure, are the sole rudiments of a shell in this genus, the horny covering of which is produced at its free extremity into two cylindrical processes. In the genus *Cineras*, the external tunic is strengthened by five calcareous bars, two at the ventral fissure, giving outlet to the arms, two along the terminal margin of the tunic, and one along the dorsal aspect. In the common Barnacle (*Lepas anatifera*), the calcareous matter extends from five centres, so as to protect the whole of the body, which is appended to the peduncle; the cephalic pair of valves, or that which is attached to the peduncle and defends the head, is the largest; the single dorsal piece has been compared by Cuvier, who retained the Cirripedes among the Mollusca, with the symmetrical dorsal-valve in the shell of the Pholas. All the valves are strongly marked with lines of growth, formed by successive additions to their margins, as in the shells of Mollusca. In the Pollicipes, there are other smaller calcareous plates arranged round the junction of the body with the peduncle.

All the sessile Cirripedes are strongly defended by a multivalve conical shell. The base of the shell is usually formed by a calcareous plate, and the walls are apparently divided into twelve conical compartments, six of which rise from the margin of the base, and terminate in a point at the free margin of the shell; whilst the other six, in the form of inverted cones, occupy the interspaces of the preceding series. This calcareous citadel is divided into six pieces by six sutures; the symmetry or bilaterality of the shell is determined by the dorsal piece being actually what each of the six pieces of the first series seem to be, viz., a simple triangular plate with its apex upwards; the two lateral pieces on each side consist each of the erect and inverted triangular piece closely united together; the ventral piece consists of one erect and two inverted triangular pieces, united inseparably in the mature Balanus. The whole shell has a cellular and organised texture, and its gradual expansion is provided for by the successive growth and calcification of processes of the mantle which penetrate the uniting sutures. The cone is lengthened and widened below by successive additions to its base, and is widened superiorly by the gradual increase in breadth of the wedge-shaped pieces of the second or inverted series. In the *Tubicinella*, (showing Prep. No. 279,) a parasitic balanoid of the whale, the compound shell is a long subcylindrical tube, reminding us of that of an amphitrite, but the animal, in both sessile and pedunculate Cirripedes, is fixed to the bottom of the shell with the head downwards.

Although the Cirripedes in their mature state possess no distinct organs of sight or hearing, yet they are endowed with sufficiently acute sensation to retract their cirri, and, if sessile, to close their opercules, at the sound or vibration of an approaching footstep; the same actions indicate that they appreciate the atmospheric movements produced by the approximation of the hand, even, according to Dr. Coldstream, when it is not brought nearer the shells than twelve or fourteen inches.

The marine animalcules brought to the mouth by the currents of the cirrigerous feet and seized by the lateral jaws, are conveyed by a short œsophagus to a dilated stomach, which receives the ducts of two salivary glands. Groups of hepatic cæca are developed from the walls of the stomach. The intestine is bent upon the stomach, and tapers with a slightly sinuous course to terminate at the base of the caudal appendage. According to M. St. Ange, the intestinal canal of the *Lepas* contains a membranous tube, which is continued above into the secerning cells in the walls of the stomach; it may be the detached epithelium; it has been deemed analogous to the typhlosole in the earth-worm's intestine.

A dorsal vessel and circulating currents along a double canal in the arms have been recognised; but the circulating system has not been thoroughly investigated. In the pedunculated Cirripedes slender conical branchiæ are attached to the base of the maxillary foot, and to that of some of the cirrigerous feet. The ordinal distinction between the pedunculated and sessile Cirripedes is not less strongly manifested by their outward forms than by the branchial organs, which, in the Balanoids, consist of two or more broad, transversely plicated, vascular membranes, attached to the inner surface of the mantle.

The organs of generation in the Cirripedes have been differently described by different authors. If the Cirripede be diœcious, and the males be free and of a disproportionately minute size, as in the Epizoa and in most Entomostraca, to which the Cirripedes are closely allied, we must then regard the organs of generation in the large attached individuals under a different and more simple point of view than they have hitherto been described. The males are, however, wholly hypothetical. In the pedunculated Cirripede, a large granular, glandular mass covers the viscera immediately beneath the muscular tunic of the body, extending from the mouth to the anus. Its numerous ducts successively unite into three or four principal trunks, which terminate in a lateral receptacle at the side of the intestine. In *Lepas* a duct is continued from this receptacle on each side, which ducts unite to form a common tube, which passes through the canal of the extensile tail. In *Otion* the two canals are continued distinct to the extremity of the pro- The walls of the receptacle, which is the common termination of the ducts of the lateral glandular body, are thick and glandular.

According to Cuvier and Dr. Burmeister, these glandular parietes of the ducts of the gland constitute the testis, and the glandular mass itself is the ovary. The ova are impregnated in the course of their passage through the common receptacle, and the duct continued from it.

On the diœcious hypothesis, we must suppose that the large fixed individuals are females; that the ovarium exists under the form and situation in which it is described by Cuvier; and that the supposed testis, which makes its appearance in a very questionable form as a glandular tunic of the oviduct, is actually a nidimental gland, and adds an exterior covering to the essential part of the ovum.

But ova are certainly developed in the pulpy substance of the peduncle. These, however, in Cuvier's view of the organs, are supposed to be impregnated ova, conveyed by the extensile tail or ovipositor into the cellular texture of the peduncle. On the diœcious hypothesis, the ova of the peduncle must also be supposed to be conveyed by the ovipositor from the lateral ovaria, but to be impregnated by the males *in transitu*.

The organs of both sexes are, however, combined in the same individual: the part described by Cuvier as the ovarium is the testis; the dilated canal into which its ducts converge is a spermatic receptacle; its glandular walls a prostatic organ; and the terminal flexible and extensile tube the penis. The true ovarium is situated in the peduncle, to the soft tissue of which the ova unquestionably adhere when first developed. It is here that they acquire the azure or violet-coloured yolk; and from this part they subsequently pass into two leaf-shaped receptacles, placed one on each side, between the body of the animal and the lining membrane of the shell. The ova are doubtless impregnated in attaining this situation: here they increase in size, and change their colour to pink and then to white: the embryos are here developed, and, after their escape, all traces of the temporary receptacles disappear.

When we reflect on the uniformity of distribution of the Cirripedes, particular species being attached to particular objects, and these not always stationary and extended bodies, but often living animals, and sometimes animals with quick powers of locomotion; when we further call to mind that they adhere, not by prehensile jaws or feet, but by the growth of a pedunculated root, or by the gradual application of a layer of cement forming the base of their shell, we must be convinced, that the organisation and properties of the sedentary Cirripede are wholly inadequate to afford an insight into the process by which it acquired its resting place, and that a knowledge of its previous career from the time of quitting the egg is not less essential to an explanation of the subsequent attachment of the *Cirripedia*, than it was for the elucidation of corresponding phenomena in the *Epizoa*.

No fortuitous dispersion of ova giving origin at once to a pedunculated or sessile multivalve can account for the invariable attachment of the *Coronula* to the skin of the whale, and of the *Otion* to the shell of the parasitic *Coronula*; of the *Chelonobia* to the carapace of the turtle, of the *Cineras* to the tail of the sea-serpent, or of the imbedding of the *Acasta* in the substance of a sponge. These re-

markable phenomena have been explicable only since the discovery of the singular metamorphoses which the Cirripedes undergo, and of the power which they possess, at one period of their existence, of attaining and selecting their peculiar and appropriate place of permanent abode. Nor were the real nature and affinities of this singular shell-covered class of animals less problematical and doubtful before the phenomena of their development had been traced out.

Mr. V. Thompson, whose minute and careful researches into the natural history of marine animalcules have thrown much light on the structure and development of radiated animals, was also rewarded by the discovery of the metamorphosis of the Cirripedes. On the 28th April, 1823, he captured, with a small muslin towing net, a number of translucent animalcules, about the tenth of an inch in length, of a sub-elliptic form, slightly compressed, and of a brownish tint; the body of each was defended by a shell composed of two valves, joined by a hinge along the back, and opening along the opposite margin for the protrusion of a large and strong anterior pair of limbs, provided with an adhesive sucker and hooks, and of six pairs of posterior jointed members, terminated by a pencil of bristles. These natatory limbs acted in concert, so as to cause the animal to swim by a succession of bounds like the water-fleas (*Daphnia*). The body was terminated by a short tail, composed of two setigerous joints. A pair of pedunculated compound eyes was attached to the anterior and lateral part of the body. Other specimens of this little seeming crustaceous animal were taken on the 1st of May, and preserved alive in a glass vessel of sea-water. On the night of the eighth two of them had thrown off their outer skin, and were firmly adhering to the bottom of the vessel, where they rapidly assumed the form of the young of the sessile Barnacle called *Balanus pusillus*. The sutures between the valves of the shell and of the operculum were visible, and the arms, though not yet perfectly developed, were seen moving within. The eyes also were still perceptible, although the principal part of the black colouring matter appeared to have been thrown off with the exuvium. On the 10th of May another individual was seen in the act of throwing off its exuvium, and attaching itself to the bottom of the glass. As the calcification of the shell proceeds, the eyes gradually disappear, and the visual ray is extinguished for the remainder of the animal's life. The arms at the same time acquire their usual ciliated structure.

The *Lepas*, in its transitory locomotive stage, does not, like the young *Balani*, resemble the bivalve *Ostracoda*, but rather approximates to the genus *Cyclops*. It has a single median sessile eye-speck, three pairs of members, the most anterior of which are simple, the others bifid. The back of the animal is covered, like the *Argulus armiger*, by an ample shield, terminating anteriorly in two extended horns, and posteriorly in a simple elongated spinous process.

The discoveries of Mr. Thompson have been confirmed by Audouin, Wagner, and Burmeister. The latter entomologist divides the development of the Cirripedes into five stages. The first is that of the ovum; the second of the locomotive embryo; the third when the young attaches itself, and becomes encased in a shell; in the fourth stage it gradually assumes the character of the adult; and the fifth stage is that of perfect development.

The locomotive embryo is developed before the ovum quits the parent; the shell, in the first stage of its growth, is coriaceous, and formed of one piece, which is placed on the back. The organs by which the young animal fixes itself are the long antennæ, or setigerous legs, situated near the mouth; in the *Lepas anatifera* the peduncle is formed by a sac-shaped process of the mantle filled with yellowish matter.

The general course of this metamorphosis, and the enjoyment of locomotive and visual organs for a brief period, which are wholly denied to the full-grown animal, characterise a condition which is closely analogous to that of the young in the Epizoa, in the Trematoda, and in the Polypi.

LECTURES ON THE CHEMISTRY OF THE POISONS; OR, ON PRACTICAL TOXICOLOGY.

SHOWING THE APPLICATIONS OF CHEMISTRY TO THE DISCOVERY OF CRIME.

By H. LETHEBY, M.B., Lond:
Lecturer on Chemistry at the Medical College of the London Hospital.

LECTURE V.

Action of sulphuric acid on animal substances.—On strong solutions of albumen.—On weak solutions of ditto.—On the serum of blood.—On mucous membranes.—On woollen cloth.—Composition of sulphate of albumen.—Tests for sulphuric acid.—Its taste.—Its action on litmus.—Its action on the soluble salts of lime, lead, barytes, &c.—The fallacies of these tests.—Presence of sulphates in the liquid.—Modes suggested for the recognition of free sulphuric acid.—Quantitative determination of this acid.

GENTLEMEN,—We will continue our inquiries into the action of sulphuric acid on organic compounds; and, before we proceed to investigate its influence on animal substances, I ought to mention, that strong sulphuric acid has the power of striking a blood-red colour with salicine, a neutral substance which is obtained from willow bark; it even exerts this action on the inner surface of the willow bark itself; but this character, although it is a very peculiar one, is not of any value in a medico-legal point of view; for an acid which has a specific gravity of 1616, and which contains as much as 62 per cent. of anhydrous acid, is far too weak for the manifestation of this peculiar re-action.

Again: you will find, that when strong sulphuric acid is heated on a few crystals of gallic or tannic acid, it acquires an orange red colour; but, as in the last case, the acid must be concentrated, in order to obtain this effect. We will now examine the mode in which sulphuric acid acts on animal substances.

(a) *Action of the acid on strong solutions of albumen*; that is, on the undiluted white of egg. If oil of vitriol, having a specific gravity above 1830, be poured on this kind of albumen, the acid will instantly coagulate it, and convert it into a white opaque mass, which has the appearance of boiled white of egg. In a few minutes, however, the albumen will begin to blacken along the line where it touches the oil of vitriol; and, if we allow the mixture to stand for an hour or so, the albumen will dissolve and form a yellowish brown liquid, having the peculiar odour of sulphurous acid. This re-action is very manifest, even with a solution of sulphuric acid, which has a specific gravity as low as 1546, and which contains no more than 55 per cent. of anhydrous acid; but, in such a case, the acid requires a longer time for the subsequent solution of the albumen. Acids which are weaker than the preceding, are deprived, in a great measure, of their solutive power; for, if we take an acid whose density is not greater than 1400, although it will instantly coagulate the undiluted white of egg, yet the coagulum will retain its white colour, and remain undissolved, even after the lapse of twenty-four hours.

With regard to the point at which the dilute acid loses its power of coagulating white of egg, it may be said, that, an acid having the density of 1·136 requires about fifteen minutes for the full manifestation of this change, and that a weaker acid, as for example, one having the specific gravity of 1·005, and which contains only 0·41 per cent. of dry acid will act upon strong liquid albumen and partially coagulate it after a period of about two hours. Acids which are weaker than this are almost entirely without action on albuminous compounds.

(b) *Action of Sulphuric Acid on Weaker Solutions of Albumen*—that is, on solutions which are made by mixing the white of one egg with an ounce of water. The albumen of this solution is instantly coagulated by acids which have a specific gravity above 1·390; but weaker acids require time for the full manifestation of this action; and solutions of sulphuric acid lose their power of precipitating albumen when they are diluted so as to contain only about 1 per cent. of dry acid—that is when they are diluted so as to have a density below 1010.

(c) *Action of Sulphuric Acid on the Serum of Blood.*—The operation of oil of vitriol upon serum is very similar to that which occurs when the acid is added to strong solutions of white of egg. For example—If we use an acid which has a density above 1830, it will instantly coagulate, then carbonise, and in a few minutes dissolve the albumen o serum, so that the last-named action takes place a little more quickly than it does in the case of oval-bumen. The same change occurs when we employ weaker acids, as, for instance, those which have a density as low as 1390; but they require time for the manifestation of this effect. More dilute solutions of sulphuric acid act merely as coagulants, and they even lose this power when they are reduced to the specific gravity of 1008, that is when they contain only about 0·8 per cent. of anhydrous acid.

(d) *Action of the Acid on Dead Mucous Membrane.*—Almost every kind of dilute sulphuric acid instantly produces a whitening effect when it is poured upon a mucous surface. This coagulating action is well marked when we employ an acid which has a density of about 1500. On such occasions the mucous membrane immediately acquires an opaque pearly white appearance, which strongly resembles a coating of white paint. Acids which are weaker than the preceding merely render the surface of the membrane dull and opalescent. On allowing a tolerably large quantity of sulphuric acid to remain on the membrane for a few minutes, you may remark that the strong acids rapidly corrode and carbonize it, and that the weak ones produce a darkening effect only when the tissues of the part are gorged with blood. This effect does not result from any carbonizing power possessed by the dilute acid, but from the property which they have of acting upon the colouring matter of the blood, and of converting it into a dark grumous-looking compound.

In all cases in which oil of vitriol is allowed to act on animal tissues, we find that it combines so intimately with their albuminous elements, that it cannot be dissolved out by the ordinary processes of lixivation. To illustrate this fact we will take about a drachm of strong oil of vitriol and pour it into the cavity of a stomach. We will then move the viscus about so as to diffuse the acid as freely as possible over its surface, and allow it to stand for a few minutes. At the end of this time the acid will have combined with the tissues of the organ, and have formed a compound which cannot be removed by mere washing; for, on pouring a little water into the stomach, and then testing the liquor so obtained, you will perceive that the greater portion of the acid has disappeared. This is a very important fact, and it is proper that you should bear it in mind in all cases of poisoning by sulphuric acid, lest you be deceived or disappointed if you fail to recognise the presence of the free acid in the contents of the stomach; for, as I shall bye-and-by inform you, there are cases on record in which large quantities of oil of vitriol were swallowed, and in which the effects of the acid were most clearly exhibited on the membrane of the lips, tongue, œsophagus, and intestines, notwithstanding that the search for the acid in the contents of the alimentary canal was most unsuccessful.

(e) *Action of Sulphuric Acid on Woollen Cloth.*—Those acids which have a density above 1830 act immediately on all kinds of woollen fabrics, and render them of a dirty brown colour. In twenty-four hours the colour becomes somewhat paler, and the cloth looks damp and feels rotten, for it gives way before the slightest force. The weaker acids do not act so promptly; in fact, an acid having the density of 1546 requires about fifteen minutes, in order to exhibit its carbonizing action on white woollen cloth; and when the density of the acid is as low as 1136, the cloth merely acquires a pinkish tinge after an interval of twelve hours, but in all cases the fabric looks damp, and becomes exceedingly rotten.

As in the preceding instances, we find, that, when a given amount of oil of vitriol is poured upon a woollen tissue, it combines with the albumen thereof,

and cannot then be entirely recovered by the ordinary process of washing. In fact, the whole of our inquiries into the action of sulphuric acid on albuminous matters are sufficient to show that the acid combines with them in a very intimate manner, and produces a compound which is very insoluble in water. I am not exactly prepared to tell you what is the nature of this compound, whether it be, as some suppose, a hypo-sulphate of albumen, or whether it be, as Mulder thinks, a sulphate of albumen; but this I know, that the white coagula which are produced by the addition of sulphuric acid to egg albumen will yield from 6 to 10 per cent. of sulphuric acid; the larger amount being furnished by the precipitate which is found when sulphuric acid is poured into a dilute solution of albumen. These results differ somewhat from the analyses which have been published by Professor Mülder, who, in speaking of the compounds of sulphuric acid with albumen, caseine, &c., says, that the capacity of saturation for white of egg and protein for acids is essentially the same, and that the sulphates of albumen, crystalline, and caseine sensibly correspond; that, for example, sulphate of albumen furnishes 8·3 per cent. of sulphuric acid; sulphate of crystalline, 8·63 per cent.; and sulphate of caseine, 8·45 per cent. of this acid; so that, according to the Dutch Professor, sulphate of albumen corresponds to the formula $C_{36} H_{25} N_4 O_{10} + (0{\cdot}4 \; SNH_2) + SO_3 + HO$. It is, however, sufficient for our purpose to remember, that the contact of sulphuric acid with the animal tissues gives rise to the formation of chemical compounds, from which the acid cannot be washed away; and that, while this circumstance often prevents us from recognising the presence of free sulphuric acid in the liquors removed from the stomach of an individual who has suffered from the effects of oil of vitriol, so it also serves to prevent the acid from escaping from the body, and thus enables the chemist to discover the cause of death, and, perhaps, to lay bare the act of the murderer.

We will now pass on to the consideration of another part of our subject, viz.:

THE TESTS FOR SULPHURIC ACID.

These I shall discuss in the order of their delicacy.

(a) *The Taste of the Acid.*—Strong oil of vitriol has a powerful acid, corrosive taste, and produces a burning sensation wherever it touches the mucous membrane of the lips or mouth; indeed, the acidity of this liquid is so great, that it imparts a sour taste to water when the latter fluid only contains the 1-1000th part of anhydrous acid; but you will also notice that solutions which contain a smaller proportion of free acid are not readily distinguishable by this test.

(b) *The Reddening Action of the Acid on Litmus Paper.*—This test is somewhat more delicate than the preceding; for, as I have already said, it acts distinctly when the acid is diluted with 6000 parts of water; the test fails, however, when the solutions are weaker than this.

(c) *Its Action on a Saturated Solution of Chloride of Calcium.*—Acids which have a density above 1002, or which contain more than 0.2 per cent. of sulphuric acid, give a copious white precipitate with this calcareous solution. The precipitate consists of minute, silky crystals of the hydrated sulphate of lime, the formula for which is $Ca\,O + SO_3 + 2HO$. This precipitate is insoluble in dilute nitric and muriatic acids. A turbidity due to sulphate of lime is evident even when the acid is diluted so as to contain only 0·014 per cent. of real acid; but the test ceases to be of value when the solutions are weaker than this. Again, in operating with a solution of the last-named strength, it is necessary that you should use about thirty drops of it; so that it is possible to recognise by means of this test the 1-238th of a grain of sulphuric acid.

(d) *Action of the Acid on a Saturated Solution of Sugar of Lead.*—The soluble salts of lead produce a white precipitate (sulphate of lead, $Pb\,O + SO_3$) with sulphuric acid; and, like the preceding, the precipitate is insoluble in dilute acids. This reaction is very manifest when the liquid does not contain more than 0·0128 per cent. of dry acid; and, by using about thirty drops of such a liquid, we may detect as small a quantity as the 1-260th of a grain of free sulphuric acid.

(e) *Action of the Acid on a Soluble Salt of Baryta.*—Chloride of barium produces a white precipitate (sulphate of baryta) with solutions which contain sulphuric acid, and the precipitate is perfectly insoluble in nitric and muriatic acids. This is by far the most delicate test for sulphuric acid; for a soluble barytic salt will occasion an opalescence in a liquid which does not contain more than 0·0016 per cent. of the real acid; that is, when the solution is diluted so as to contain only 1 part of acid in 62,500 of water. And with regard to the quantity of acid which is discoverable by this means, you may perceive that the precipitate is evident when we use about thirty drops of the last-named liquid. Consequently the test is capable of making manifest the 1-2083th of a grain of sulphuric acid.

Fallacies of these Tests.—The phosphates, carbonates, sulphates, iodates, and, as Mr. Taylor says, the seleniates, and fluosilicates give rise to precipitates which are very similar to those occasioned by sulphuric acid; but independent of the fact, that the precipitates obtained by the first-named compounds are all soluble in nitric or muriatic acids, a property which is sufficient at once to distinguish them from the sulphates, you will notice that all these compounds, excepting the first two, are rare substances, and are not likely to be met with in the contents of the human stomach, or, indeed, in any place but the laboratory of the scientific chemist; they can scarcely, therefore, as Dr. Christison remarks, be considered as sources of fallacy. There is, however, another, and a very positive character whereby the sulphates of lime, lead, and baryta may be readily distinguished. This character is especially applicable to the recognition of sulphate of baryta, and it is founded on the property which this salt has of being reduced at a white heat, by carbonaceous matter. In order to make it manifest, we proceed as follows:—Collect the precipitate which is obtained by means of a barytic salt; dry it, and mix it with about four times its bulk of powdered wood charcoal; fold up the mixture in a piece of platinum foil, and ignite it for a few minutes before the mouth blowpipe; when the foil is cold, unwrap it, and put its contents into a small test tube; then add a few drops of diluted muriatic acid, (1 to 1,) and apply heat; sulphuretted hydrogen will be evolved, which is known by its unpleasant odour, and by its darkening a strip of paper which has been moistened with a solution of sugar of lead. The rationale of this test is the following:—When sulphate of baryta is heated with carbonaceous matter it loses its oxygen, and becomes changed into sulphuret of barium. This compound is, in its turn, decomposed by the muriatic acid, and converted into chloride of barium with the evolution of sulphuretted hydrogen gas. I find that this test is a very delicate one, and that its re-actions are very manifest when we employ no more than the 1-10th of a grain of sulphate of baryta, a quantity which is yielded by the 1·29th of a grain of sulphuric acid.

Another, and a very great source of fallacy with which you will have to contend in the course of your operations, is the presence of a soluble sulphate in the liquid which you are analysing; for you are to bear in mind that sulphates are very commonly present in organic liquids, and that the tests which we have just gone over, are applicable, not only to the detection of free sulphuric acid, but also to the recognition of this acid in every one of its ordinary forms of combination. In fact, the tests give rise to the very same re-actions when we are operating on solutions which merely contain Epsom salts, Glauber salts, sulphate of zinc, alum, or, indeed, any other common kind of sulphate. It is, therefore, a matter of the gravest importance that we should guard against these sources of fallacy; and that we should know *how to distinguish the free acid from that which is in combination.* You will readily perceive that this is a most important problem; for to repeat my observations, while, in the first place, the quantity of acid detectable in the contents of the stomach, in a case of poisoning, is very small, so, in the second place, the re-actions by which the chemist is ordinarily guided in such cases, will be sure to be manifested whenever a sulphate, and perhaps a common one happens to be present in the alimentary canal. I cannot say, however, that this important problem has yet been satisfactorily solved, notwithstanding that many suggestions have been offered for the purpose of accomplishing so desirable an object. Among these suggestions are the following:—

1. It has been proposed that we should evaporate the suspected solution to dryness, and observe whether there be any saline residue or not; for it is said, that in the case of free sulphuric acid the solution will be entirely volatalised by such a process; but that if a sulphate be present it will be made evident by the fixed residuum. This process, however, although it appears to be so simple and conclusive, is only applicable to the detection of the free acid in pure and unmixed solutions; for, if we proceed to apply it in cases where the liquids contain organic, or even other saline matters, we shall find that it is open to many objections, and may often lead to very erroneous conclusions. I will give you one case by way of illustration. Most organic solutions contain alkaline chlorides, and if we operate upon such a solution, having previously added to it a few drops of sulphuric acid, you will notice that there is left a fixed residuum of alkaline sulphates, and that the result of the process indicates the presence, not of free, but of combined sulphuric acid.

2. It has been proposed by some chemists that we should shake up the doubtful liquid with a small quantity of finely powdered carbonate of baryta, in the hope that the soluble sulphates will not act on this barytic compound, and that the free acid will. You may perceive, however, from the results of the experiments which are now before you, that alum, sal-enixum, Glauber's salt, Epsom salt, sulphate of zinc, and, indeed, every one of the common sulphates, will easily re-act on carbonate of baryta, and give rise to the formation of the sulphate of this base; and if it should happen that a little free acid of any kind be present in the liquid, the re-actions will be much more prompt and energetic. Let me demonstrate the truth of all this to you. Into each of these glasses I have placed a small portion of carbonate of baryta; and I have poured upon the first portion a weak solution of alum, upon the second a solution of sal-enixum, upon the third a solution of Glauber's salt, upon the fourth a solution of Epsom salt, and upon the fifth a solution of sulphate of zinc. These solutions have been standing upon the carbonate for about one hour, and now, if you carefully wash the precipitate which is at the bottom of each of the glasses, and then test it with dilute nitric acid, you will perceive that every one of the deposits is insoluble in this menstruum; showing that in each of these cases the carbonate of baryta has been converted into sulphate, and that the process is, therefore, not at all applicable to the recognition of free sulphuric acid.

3. If we employ, as Dr. Christison formerly suggested, carbonate of lead instead of carbonate of baryta, we shall find that the re-actions are very similar to those which we have just witnessed, excepting, perhaps, that the soluble neutral sulphates are not so easily decomposed by carbonate of lead as they are by carbonate of baryta.

4. Some chemists have proposed to adopt a more complicated process, in order to determine the presence of free sulphuric acid; for they recommend that we should take two equal portions of the suspected liquid, and treat them in the following manner.

One portion is to be acidulated with nitric acid, and precipitated with a salt of baryta.

The other portion is to be evaporated to dryness, its residuum re-dissolved in water, acidulated with nitric acid, and then precipitated with a salt of baryta.

By operating in this manner, and comparing the results of the two experiments, it is presumed that we may determine the presence of free sulphuric acid with much certainty; for, in the first case, the weight of the sulphate of baryta indicates the total

amount of acid present in the liquid, and, in the second case, the free acid having been volatilised during the process of drying, the weight of the barytic compound only indicates the amount of combined acid; so that, by subtracting the weight of the one from that of the other, we obtain a number from which we may calculate the amount of free acid originally present in the liquid. A little reflection, however, will show that the following objections may be raised to this process:—1st. A supersulphate, or even a small quantity of alum may, by drying the residue too far, give rise to results which indicate the presence of free acid. 2nd. If the evaporation of the liquid has been conducted with haste, that is, if it has been permitted to go on with active ebullition, some of the sulphates will be lost during the process, and the results will lead to a false inference. 3rd. If it should happen that an alkaline chloride is dissolved in the liquid, the free acid, if any be present, will combine with the alkaline base, and so, by becoming fixed, it will lead to an erroneous conclusion.

5. Simon has proposed to evaporate the liquid nearly to dryness, and to digest the residue in absolute alcohol, in the expectation that this menstruum will only take up the free acid, and will leave all the sulphates in an insoluble form. This expectation is to a certain extent founded on fact; but you may remark that alcohol instantly removes sulphuric acid from the supersulphates, and that it will even dissolve a small quantity of the neutral salts of this acid, provided it be digested on them for a few hours. Moreover, the evaporation of the liquid is open to the objections just mentioned.

6. Orfila directs that the concentrated liquid should be agitated with pure sulphuric ether, and that the ether should be decanted, and allowed to evaporate spontaneously; for (says this Author) ether will dissolve free sulphuric acid, and will leave the neutral and supersulphates untouched; but, as Dr. Christison very justly remarks, this proposal is unaccountable, for Simon stated in his paper, three years before, that ether does not remove sulphuric acid from watery fluids containing it; and Dr. Douglas Thompson and Dr. Christison have found, on inquiring into the matter, that they could not, by means of ether, separate a particle of sulphuric acid from an ounce of rice soup and mucilage, to which ten drops of the acid had been added.

Amidst the difficulties, therefore, which beset this question, you will very naturally inquire how you are to proceed, in order to determine the presence of free sulphuric acid in any mixture. Now, although I cannot, as I said before, give you a very satisfactory answer to this question, yet I can lay before you a few facts, whereupon your judgments in this matter may be safely based.

Firstly,—If the mixture be a pure and colourless one, you are to evaporate it until it has a density of about 1·140; and then, on boiling it for a few minutes with a grain or two of sugar, you will notice that, if it contain free sulphuric acid, it will acquire an amber tint, and, perhaps, a deep brown one; while if it merely contain a sulphate, or supersulphate, it will not manifest this re-action, but will remain colourless. Again, I find that, by evaporating the liquid until it has a density of about 1·600, and then heating it with a few grains of metallic copper, it will, if it contain the acid in a free state, evolve the vapour of sulphurous acid; but it will not do so if it merely contain a sulphate or supersulphate.

Secondly,—If the mixture contain organic matter, or an alkaline chloride, the process is not so simple, and the conclusions are not so definite; for we can only obtain results which are near to the truth. I believe, however, that in these cases the process of Simon will be found to be the best. I, therefore, advise you to adopt it; but I shall postpone the description of this process until we consider the means whereby sulphuric acid is to be detected in organic mixtures.

Quantitative determination of Sulphuric Acid.—You have just become acquainted with the difficulties which stand in the way of our detecting free sulphuric acid in any compound mixture; but if we are manipulating with a liquid which only contains sulphuric acid and sulphates, we can easily determine the proportion of free acid present in it for, by using a solution which contains a known amount of pure anhydrous carbonate of soda, that is, of carbonate of soda which has been recently ignited, and adding this solution to the acid liquor until it just ceases to affect litmus paper, we can readily calculate the saturating power of the liquid, and hence the proportion of free sulphuric contained in it; for it is known that every 53 parts of the ignited carbonate of soda represents 40 parts of free anhydrous sulphuric acid. Supposing, therefore, that we have employed 100 grains of a liquid containing free oil of vitriol, and that it required 364 parts by measure of a solution containing 53 grains of dry carbonate of soda in every 160 parts of it, it is evident that such a liquid contains 91 per cent. of free acid; for as 160 (containing 53 grains of carbonate of soda) is to 40 grains of sulphuric acid, so is 364 parts to 91. Or, to make the calculation a little more simple, as the solution of carbonate of soda has been made of such a strength that every 4 parts of it represent 1 grain of sulphuric acid, we have only to divide the quantity of the solution used by 4, and the product is the amount of free sulphuric acid contained in the liquid.

Another and a more accurate mode of determining the total amount of acid, free and combined, in any liquid, is the following. Acidulate the liquid with nitric acid, and then add an excess of some soluble salt of baryta; collect the precipitate and dry it. Every 117 grains of the sulphate of baryta so formed is equal to 40 grains of sulphuric acid—quantities which are very nearly in the proportion of 3 to 1.

LECTURES ON MATERIA MEDICA,

DELIVERED AT THE ROYAL COLLEGE OF PHYSICIANS.

By GOLDING BIRD, M.D., F.R.S.,
Materia Medica Professor to the College.

LECTURE VI.

MATERIA MEDICA.

Mr. President and Gentlemen,—I will here relate an experiment which I performed with the assistance of an indefatigable votary of medical science. I assumed, that the assimilative force was enjoyed by the vegetable as well as the animal,—that it behoved Nature thus to endow the lowest as well as the highest; and therefore it occurred to me, that if there was evidence of the first exerting an influence on lower organisms, it would be satisfactory so far as it goes. I will not venture to say, that I have seen its influence on very low organisms. A piece of the nitella, that beautiful plant, used for the purpose of watching the circulation of the cells, was placed in a glass vessel, and while watching it, I observed a curious circulation of the sac globules in one part of the cell; we found that this was under the influence of certain agents which were incapable of any chemical action. Thus, morphia sent the circulation to sleep, and in few minutes it stopped; hydrocyanic acid stopped it in a moment; strychnia quickened it, and then stopped it. Now, whatever influence they exerted, it was not any chemical action on the constituents of the cell. It then became a question, whether the intenseness of the bitter of morphia had anything to do with it. I would not attach much worth to this fact; but, whilst it is evident that some of these narcotics exert an influence in narcotising the life of a plant; yet some did not do this, and kept the plant in perfect vigour. It is simply a curious observation.

The third class which I have enumerated is one which has been largely employed during almost all ages, and contains a small number characterised by the combination of a peculiar bitter substance, chrystalline, neutral, free from nitrogen, but combined with a quantity of starchy matter of a low form. To this class we refer the leaves of the coltsfoot, Iceland moss, and the cock-moss of our heaths, —given to children as nutrient tonics in cachexia. Here also is included the well-known sarsaparilla and hemidesmus, which was once used very largely without discovering that it was not sarsaparilla. Here, then, I recommend a class which, while it aids the function of assimilation, gives also a nutrient principle; and hence the undeniable value of the three latter in chronic cachexia.

But there is another class which has an influence of a remarkable character, and acts in aiding the resisting force, seen in a marked manner to stimulate this function, and enabling it to throw off poisons developed during the decomposition of vegetable matter, as in marsh malaria. The conditions under which this is developed is nearly the same. It was supposed, that this gave a development of sulphuretted hydrogen; but it is not so. Professor Daniel, in adverting to this, had some water collected off the coast of Africa and brought to Europe; it contained sulphuretted hydrogen; and a series of observations were published in America. He took coins and hung them up under the influence of the water, and they were all corroded in a night. The explanation was, that the sea water had been corked up with animal and vegetable matter; thus decomposition went on; oxygen was removed; sulphurets withdrawn, and sulphate evolved. Any sea-water would have done the same. Whatever be the cause of marsh malaria, a certain change takes place in the blood; the peculiar whity-brown complexion is not to be mistaken, and we know the certain effects under which patients sink. This poison exerts a character termed periodicity. Now, there are a class of tonics which have the effect of opposing this: but, we find them of such different characters, that we ask with some surprise how they have come to be connected. The influence of barks is well-known. They act by giving a large amount of energy to the resisting force, and thus get rid of a large proportion of the poison which may exist in the blood. They have one character in common—they have all an influence in giving vigour to the depressed nervous functions. We have evidence that these peculiar remedies control the chemistry of the body. The influence of arsenic in the treatment of disease resulting from disordered capillary circulation is well known; it owes its influence to its power of stimulating the force of resistance, and in enabling the body to get rid of poison. Berberine is also recommended, having had a large trial in England, and never failed in stopping ague, when properly prepared; if a patient comes with an unprepared system, it is better to give mercurials first, and then berberine.

The fifth class are remarkable on account of its stimulating the nervous function properly so called. They have many properties in common. The influence of zinc no one will deny. In a case of chorea, where the patient has lost all control over the nerves of voluntary motion, or a school-child frightened—let that child endeavour to control its movements; it will be found useless,—there is a loss of control;—and here zinc exerts an astonishing influence, and you may increase the dose to almost any quantity. Silver and copper are analogous so far. Strychnia is supposed to stimulate the influence over the spinal chord; that it exalts the nervous power is undeniable; but is also capable in small doses of exerting a most decidedly strengthening influence in chorea. I tried it in one case which had resisted zinc, and the patient got perfectly well. But there is a curious illustration of the power of strychnia in controlling debility, in cases of irritable stomach,—that condition which we often see in hysteria, and other circumstances. When a calculus is passing, this irritation is felt. Now, in such cases strychnia acts almost as a charm, and if asked to name a remedy of which there was more certainty than any other, I should at once recommend strychnia, in 1-12 or grain doses. Hitherto I have supposed that these stimulate no particular function; but there is one class which have a decidedly stimulant influence on the active force. These are the Stimulants—*quoad*, the stomach; *quoad*, the skin; *quoad*, the intestines.

Quoad, the stomach. Here we have a bitter principle, with the addition of an aromatic essential oil, exciting the active force and stimulating the

force of vital resistance. Hence the use of these in aiding the force of assimilation; and these stimulating the secretion of gastric juice, exert an influence not shared by simple tonics.

Quoad the skin; which, while they exert an influence as tonics, partly exert it on the skin. These were favourite remedies among the old physicians and I believe now, that if any of my colleagues were asked whether they could treat a case of fever without serpentaria, they would express some doubt. This led me particularly to watch the action of these remedies; they do to a certain extent stimulate, and one proof of this is, that bed-sores begin to show healthy aspect at the same time that the function of the skin becomes stimulated. The guiacum has a high character for opposing that depressing condition which arises from the bite of the rattlesnake but it differs from the others, in the presence of essential oil.

Quoad the intestines. These two are commonly regarded as astringents. This is a very wrong idea. They give tone to the intestines. The first is well known to do this; both excite nausea.

I am anxious to shadow forth here, that if we are to be successful in a class of remedies as tonics, there is no class so important to be well understood. To succeed, it must be by endeavouring to stimulate the forces which I believe to exist in the system, by the simple, the calmative, the nutrient, the anti-periodic, the nervin, or the stimulant.* But there is a class totally distinct from these, but equally tonics,—those which give a healthy constitution to the blood. The influence of food and oxygen is plain enough, because when oxygen is cut off, we at once observe the fearful condition of the general health; and when it is re-supplied how the powers of the body are excited. Now, in all the other classes of remedies, there is not one for which we have not a substitute. But if I am not possessed of iron, what have I? Nothing; and for this reason, that iron is a substance containing a characteristic element of the blood. Now there are certain conditions of the health in which iron is absent, as in anæmia. In certain districts where malaria abounds there is a remarkable tendency to anæmia. A Physician shall attend the Islington Dispensary, and in one or two days go to the Hospital in the Borough, and it is remarkable how anæmia abounds in the one and not in the other. To-day, 130 children were brought under twelve years of age, and a number of them were anæmic cases. This remedy is the only one for which we have no substitute; for with others you do not give the pabulum to stimulate the assimilative forces of the body, and hence the value of iron combined with a vegetable acid.

In these remarks I have alluded to a series of remedies which oppose the condition of decomposition. But we have antagonistics to these, namely, alteratives, which stimulate the chemical force, and thus enabling us to increase the destruction of tissue, the oxydation of the matter of the blood, and modifying the vital force. How, then, are we to stimulate the chemical force. Look at a patient taking alkalis; give a fat man liq. potass. in 2 drachm doses two or three times a-day; what is the result? A diminution of fat, and the emaciation of the patient. This only acts by aiding the chemical force of the body. In like manner this explains the iodide of potassium in removing certain unhealthy deposits in the glandular textures. One notion is, that it starves them; others, that it prevents the supply of growth. But I suspect, that it exerts an influence in stimulating the chemical force of the body. It is capable of exercising an influence on the fresh fibrine of the blood when out of the body, yet I have no doubt that it aids the chemical functions of the body, and as these matters, which are not developed by the vital power, will yield, so under the influence of a salt this change takes place. In this manner acetate of potass acts; also mercury, in removing unhealthy deposits in the body. We know the influence of mercury in causing the coagulum of the blood to become lacerable, and hence it is active in influencing the chemical force.

I must now break off. If I have been able here to adduce anything of interest, it would not be doing justice to take leave of you without acknowledging how much I have been indebted to the Pharmacologia of our illustrious President. The rudiment of a great deal that I have advanced will be found there, and will lose their novelty in proportion as that work is studied; there is not one line too many in that book. In conclusion, I cannot but express the fear that I have occupied your time in these six Lectures somewhat unprofitably, and would express my deep sense of the honour you have done me in the patient attention which you have given to what has been advanced.

ORIGINAL CONTRIBUTIONS.

IMPERFORATE ANUS.

SUCCESSFUL OPERATION ON THE THIRD DAY AFTER BIRTH, WITH OBSERVATIONS UPON THE CASE.

By JOHN HOOPER, M.D., L.R.C.S. Edin.; M.R.C.S. London.

On Saturday, June 16th, 1849, the wife of a clergyman, residing about five miles from this place, was delivered of a fine little boy, about 10 p.m., four weeks before the full period of gestation.

17th.—I saw both mother and child; they appeared to be doing well, the latter had not been applied to the breast; a small quantity of thin gruel had been given; no evacuation; ordered the immediate application to the mother, and, if the first milk did not move the bowels, a teaspoonful of castor oil was to be given.

18th, afternoon.—I was requested to see the child; the bowels had not acted; castor-oil had been given, and the infant had sucked; on examination, I found there was a perfect occlusion of the anus, no intumescence, nor the slightest corrugation of the skin, where the aperture should be; it was a perfectly plane and even surface; on applying the finger, it conveyed the sensation of solidity. I felt satisfied the rectum terminated at some distance within the pelvis. As it was necessary to be guarded in my prognosis, I stated what I feared to the parents; and, with their consent, made a crucial incision through the integuments to the depth of half an inch, finding the parts perfectly solid. I then, with less hesitation, pronounced a decided opinion that the child could not live without an operation; that an issue could only be obtained either by the left side of the abdomen or anus. On explaining the danger and inconveniences attached to these operations respectively, the father considered for a short time, and then decided that it would be better to attempt an opening in the direction of the usual course of the natural passage, as I thought more favourably of this attempt. Being aware of its doubtful result, he baptized the child, and I proposed coming the next day. As the abdomen was not tympanitic, distended, or painful, the postponement was desirable; for it would cause the depending part of the bowels to be distended, and pushed lower down.

19th, three o'clock, p.m.—The child has suffered much from pain and straining; when the straining occurs the nurse has frequently heard a noise like the passage of wind, and observed meconium on the napkin, which passed through the urethra. Urine comes first perfectly clear, then the meconium. The bowels are perfectly distended, the course of the colon can be distinctly seen. I determined to adopt M. Roux de Brignolles's mode of operating, which appeared to me most likely to be attended with success.

The infant was placed on the lap of the nurse, opposite the window, and held in the same manner as for the operation of lithotomy, with the shoulders low, and pelvis elevated by a cushion. An incision was made through the skin, in the exact line of the raphé, one inch in length; the incision was continued to the depth of an inch and three-quarters, through the integuments not in the axis of the pelvis, but along the concavity of the os coccygis; no vestige of the sphincter muscle or levatores ani could be seen; the substance cut through was evidently fat, with two or three nuclei-like lymphatic glands. I now introduced the index-finger of my right hand, but could not feel the distended rectum. The instrument used was a small scalpel; the edge was directed backwards.

I continued the incision until the diminished resistance indicated that I had reached the cellular tissue; the scalpel was laid aside. On introducing my finger to the bottom of the wound, which was now as deep as the finger could reach, the rectum could be indistinctly felt. I now introduced a director, up the groove of which I passed a straight bistoury; the point was turned obliquely upwards and backwards, to avoid wounding the bladder; the director was removed and pushed a little higher, when it entered the cavity of the rectum, which there was no doubt about, as the meconium began to flow. The handle was now raised, and the blade withdrawn; the intention of raising the handle is to enlarge the internal incision. The meconium began to flow freely. Injections of warm water water were now thrown up with one of Sir Charles Clarke's syringe's to wash out the intestines. During the operation the child's penis became erect, and ejected *first* a clear stream of urine, then meconium. On injecting the rectum, some of the water, discoloured with meconium, flowed through the urethra. I now introduced some fine lint, smeared with *ceratum simplex*. A quantity of air passed through the new passage; the abdomen became less inflated. During the operation the exit of wind by the urethra was audible to all in the room, and made a peculiar noise. My son, who is one of my pupils, assisted me during this operation of exploration.

Nine o'clock, p.m.—I was summoned to my patient in consequence of hæmorrhage, which had continued for two hours. The charpie had been forced out by meconium and blood; it had been reinserted before my arrival; the discharge had considerably lessened. I applied rags, wet with cold water, over the wound. About eleven o'clock there was a return of bleeding. The charpie was withdrawn, and the legs kept close together. I remained in the house all night.

20th, 5 a.m.—The nurse called me to say that the child was uneasy. He had slept soundly; been applied to the breast three times; sucked well; no hæmorrhage; napkin besmeared with meconium; portion continued to flow from the urethra; applied a pledget of lint, which had been immersed in cold water, to the wound; advised its repetition; child to be applied to the mother 7 times in 24 hours.

21st, 12 o'clock noon.—My little patient has had a tranquil night; very little meconium has passed by anus, but more by urethra; abdomen distended; I tried to introduce a bougie about two-eighths of an inch in diameter, and it would not pass into the rectum; I introduced my silver director, and tried to dilate the opening into the gut; some rather consistent fæces passed, but it was evident that the internal opening was not large enough; I now passed the straight bistoury half an inch higher than before; on withdrawing the instrument, a formed dark evacuation, about two feet in length, passed easily; the rectum was well injected with warm gruel; bowels were well emptied; the latter part of the dejection was perfectly yellow.

23rd.—Good night; no offensive matter from urethra; bowels have acted well three times daily since last report; introduced a bougie nearly an inch and a half in circumference, anointed with cerate (with perfect freedom) four inches and half, used an injection of warm gruel.

26th.—The bowels have acted well daily; the larger bougie has been introduced every morning by myself, and afternoon by nurse. Discoloured fluid passes occasionally by urethra.

30th.—Patient going on well; bowels regular; found trouble in introducing the point of bougie. Nurse confessed she had neglected to do so a second time yesterday. This is a proof how quickly the external wound contracts. Urine alone has flowed through the urethra the last three days.

July 1st.—Bowels inactive; teaspoonful of castor-oil was given this morning, which operated well. The parts around the anus, before full and promi-

nent, have become hollow and puckered, presenting more the usual appearance of the orifice.

6th.—The bougie passes easily; my little patient is labouring under aphtha infantium; the bowels are more than usually acted upon; the dejections evidently irritate the skin around the anus. Ordered

℞ Magnesiæ calcinatæ gr. iij. ter. die.

℞ Sodæ biboratis ʒj.; mellis ʒss; aq. rosæ ʒx.; fiat lotio, partibus affectis calimo scriptorio sæpe applicanda.

9th.—He has quite recovered from aphtha; going on well.

15th.—The bougie has been used twice a day up to this period; case going on exceedingly well. I said it would not be necessary for me to call for three days, and until my next visit the large bougie might be discontinued.

18th.—Bowels have been regular; considerable quantity of fungus projecting from the orifice, giving it the appearance of two cuts. I had the greatest difficulty to pass the large bougie, and almost feared it would be necessary to use the bistoury; but by a little address I succeeded, and allowed it to remain in a quarter of an hour; applied argenti nitras to the fungus; requested that the large bougie might be used twice a day in future, and dry lint applied to the anus.

23rd.—He is going on well; bowels regular; bougie has been used twice a day since last report; fungus quite destroyed. This is the 34th day.

30th.—I had not seen my patient since the 23rd; his bowels act naturally two or three times daily, and he appears thriving. The nurse has used the large bougie twice a day, introducing it only one inch, as the granulations are only troublesome at the orifice; there does not appear to be any probability of contraction taking place now. I introduced the bougie about four inches, which was followed by an evacuation of fæces and urine. If any fungus appears, the nurse is desired to apply nitras argenti and dry lint. I have taken leave of my patient, considering him convalescent. In the course of my treatment tents made of soft sponge were tried two or three times, which caused pain, and were soon forced out. I am satisfied that the perusal of treatment in this case will cause bougies to supersede the use of tents. Fortunately for mankind these cases seldom occur; when they have, with very few exceptions, Nature has had the control.

Mr. Bell operated on two cases, and said that he never met with any disease which gave him so much trouble and embarrassment. It is only by the most assiduous attention that the opening can be kept dilated. The result of my experience is, that the use of a bougie large enough to fill the aperture, and continuing to do so twice a day, will prevent the too rapid growth of granulations, and the tendency to contract.

An imperforate anus has generally some preternatural outlet, either by urethra, vagina, navel, or groin. There is an extraordinary instance of such accommodation mentioned in "Samm Med. Wahrnehen," b. viii. p. 29. A girl who from birth had an imperforate *anus* and *meatus urinarius*, and to the age of fourteen had regularly discharged her urine by the breasts, and her fæces by a natural vomiting.

Two cases of imperforate anus were communicated by Dr. Keiller to the Edinburgh Obstetric Society; (a) the first was operated upon with temporary relief; in six weeks the operation was repeated thrice, when fæculent matter ceased to pass by artificial anus; it became obliterated, and the matter passed by urethra. This ended in a complete stoppage of the fæces and urine. Death supervened. The *post mortem* evinced, that at each operation the cut had been made into the urinary bladder, into which a small and imperfect gut had been found to terminate. There was no regular rectum or sigmoid flexure. In the second case the child lived twelve weeks, and evacuated the fæces by the mouth. No operation was attempted. The colon terminated in a *cul de sac*, which floated loosely among the intestines in the umbilical region. These cases evince that there must generally be a doubt whether you will find the rectum; therefore we cannot always expect so fortunate a result as in my case.

(a) *Medical Times*. Vol. XVI. p. 532.

These cases of monstrosities or malformations are singular and various. We are perfectly ignorant of the manner in which they are generated or produced. It is exceedingly probable that they are governed by laws, regular both as to cause and effect, as in common or natural productions.

Are they primordial or aboriginal? The general opinion is that they are. If this be true, they cannot be caused subsequently by the power of the mother's imagination transferring the imperfection of some external object, or the mark of something for which she longed, and with which she was not indulged to the child of which she was pregnant. I have no doubt that many cases of malformation are primordial; but facts prove that they are frequently the consequences of strong impressions up the mind of the mother during gestation; and it is perhaps well that this opinion should prevail, in order to protect pregnant women from all hazardous and disagreeable occupations, and to secure for them more tenderness and indulgence than could be allowed in the common routine of life. The mother of my little patient, who is a very intelligent lady, suffered from *Ischuria vesicalis* at an early period of gestation. It caused her much distress, and no little mental anxiety. She endeavoured to glean information upon the subject from an Encyclopædia, and among the causes of this disease in infants, this malformation was mentioned, and, as may be supposed in a nervous lady, was likely to excite fear lest her offspring should labour under this calamity. She reasoned with herself, but could not shake off the impression.

Some years since, a lady in this neighbourhood, after giving birth to a fine child, asked me to look at the upper lip. On doing so, it presented the appearance of a well-united hare-lip; the marks of the pins were evident. About the second month of pregnancy, she saw a child who had been successfull operated upon for hare-lip.

A lady, a relative of mine, while pregnant with a boy, pinched her right thumb between the door and door-post; the accident caused her much pain. She was so firmly convinced her child's right thumb would be marked, that, at the birth, she desired the nurse to look at it, and this member appeared as if its lateral growth had been impeded by a vice, and had more the character of a finger than a thumb. He is now a man, and the deformity continues.

Dr. Wood, my predecessor, attended a lady in her confinement who had frequently, anterior to the birth of her child, affirmed, "that it would be marked with blood on the hand." About the third month of gestation, she was much frightened by a servant entering the kitchen with her hands reeking with the blood of a goose just killed. The child she bore was a girl, who is now the mother of a large family. One hand has livid spots, and, when warm, has exactly the appearance of blood having been sprinkled over it. None of her children have this mark. About eight years since, a carpenter's wife, of the name of Brand, was walking from Throcking to Chipping (two villages in this neighbourhood) during the early period of gestation; as she was passing a plantation of firs, a wild duck flew out; its sudden appearance, together with the peculiar noise those birds make alarmed her exceedingly; she saw the birds distinctly, and stood in an attitude of despair with her hands clasped for some minutes before she could proceed. Until her accouchment she continued to labour under the effects of this fright; indeed, she was an invalid during the whole period, and never without the impression that her child would have some deformity. Two surgeons were with her when she gave birth to a boy; she solicited them immediately to examine it; the fingers and toes were united by skin, and the nails had more the appearance of claws. When I first saw him, he was advanced in life, and was clearly web-footed and web-fingered; but, to give more freedom to the hand, the thumb and index finger had been partially separated by a surgeon, when he was a boy. He had one son with the same malformation whom I also saw; there can be no doubt of the aboriginality of the latter.

Did I not fear to trespass too much on your limits, I would willingly have introduced a few more cases tending to corroborate the opinion entertained by myself and others, that, although frequently primordial, monstrosity may commence at a period long after conception.

Buntingford, Herts.

PROGRESS OF MEDICAL SCIENCE.

FRANCE.

[From our own Correspondent.]

CHOLERA.

Whatever may be the influences which have given rise to the recrudescence of Asiatic cholera in London, they have extended to Paris likewise, where the disease has again manifested a tendency to the increase. This has been strongly marked during the last two weeks, and the mortality has now risen to about forty a day for the city and hospitals united. Several English visiters, who had left London in a hurried manner to avoid the complaint, were, I have been informed, attacked almost immediately after their arrival here. As to the cause of the relapse, it is impossible to offer any conjecture. All we can affirm is, that "heat" has not been the exciting or predisposing cause, for the weather is anything but warm. It is most uncertain, and at the same time unwholesome. I observe, that the disease has also returned, with more or less violence, nearly along the whole line of coast which extends from Calais to Cherbourg.

At the Academy of Medicine, the opinions seem to incline daily more and more in favour of contagion; yet when we come to examine more closely the facts adduced by the various speakers, it must be confessed that they are but feebly conclusive. At the last meeting M. Rouget de Lisle astonished the Assembly, by an account of wholesale cures performed in a manufactory, which is under his direction. All the workmen attacked were speedily cured by wrapping them in sheets dipped in boiling water, and then placing them over the boilers of the steam-engines.

This is what the French call "heroic" treatment. I question whether the "wet sheets" of Dr. E. Johnson would be found to be as efficacious.

M. Junod, on the other hand, affirms, that his monster cupping-glass is all but infallible. It is certainly a most powerful instrument for effecting derivation of the blood; and as such may be useful in preventing the internal congestions so common in cholera.

In hospital practice we have nothing of much interest this week to notice. At the large Military Hospital at Versailles, M. Baudin has been working an extensive series of experiments, for the purpose of showing that ague can be cured by arsenic, as rapidly as by quinine. The value of arsenic in the treatment of intermittents has long been known to English medical men. Here, its interest chiefly depends on the fact, that it costs 16,000*l*. *per annum* for the quinine required to treat the soldiers attacked by ague in Africa; and hence, the substitution of arsenic would effect a great economy.

At the Hotel Dieu, M. Jobert, the new luminary of that renowned *locale*, is discoursing on his favourite subject of diseases of the rectum. In a recent lecture, he made some interesting observations on fissure of the anus, and proved—"of course"—that his own method, viz., excision of the granular membrane which lines the fissure, was infinitely superior to the incisions of Boyer, the lacerations of Recamier, the subcutaneous operation of Blandin, or the cauterisations and injections of other surgeons. M. Jobert asserts that he has cured fifty patients, without a single failure, by his mode of treatment.

TREATMENT OF ANEURISM BY ELECTRO-PUNCTURE.

At the last meeting of the Academy of Medicine, M. Abeille, assistant-physician to the Val-de-Grace, read a memoir on the above subject, of which the following is a summary:—

A female, 67 years of age, was affected with a

tumour of the size of a hen's egg, which projected between the scaleni muscles and presented all the characters of aneurism. It was, in fact, a pulsating tumour, the pulsations being isochronous with those of the heart; pressure on the artery above the tumour reduced it partially in size; pressure over the tumour gave rise to a sensation of *frемissement* under the hand, and the ear detected a very sensible *bruit de souffle*. From these symptoms, and particularly from the fact, that pressure above the tumour arrested the pulsations of the axillary and radial arteries, it was concluded that the subclavian presented the anomaly of a common origin with the carotid, and ascended over the clavicle to penetrate between the scaleni muscles. All the medical men who examined the tumour were of opinion that it was arterial, and the operation of electro-puncture was accordingly performed on the 10th February, 1847. The pile employed was composed of twenty pair of zinc and copper plates; the needles were steel, four in number, 2 to 2½ inches long, and covered with an isolating mastic to within one line of the point and two of the head.

The patient having been etherized, the needles were passed into the aneurismal sac, and the battery set to work. Strong sparks were elicited, and the operation continued for 37 minutes. On awaking, the patient complained of atrocious pain, attended by convulsive movements in the muscles of the arm and wrist.

Within five minutes after the commencement of the operation the tumour began to solidify; the pulsations were less distinct, and the pulse nearly disappeared. On extracting the needles, pressure, equivalent to a weight of two pounds, was applied to the surface of the tumour. It was then quite firm and without pulsation or bellows sound. Twenty-four hours afterwards the pulse was totally absent in the radial artery; the arm was numbed and cold as symptoms of cerebral congestion manifested themselves, it became necessary to practice two bleedings. After the 4th day the tumour began to diminish in size; on the 10th day it was much smaller, and on the 18th diminished by one half. It now remained stationary for a few days, then began to diminish again, and gradually disappeared Thus, on the 37th day, the skin appeared perfectly flat; on making pressure, an oval, flattened, and firm body was felt in the place occupied by the sac; and even three months afterwards some traces of the induration could be perceived. At this period the artery had acquired a slight degree of development just above the tumour; and three branches, not before evident, and supposed to be the vertebral, inferior thyroid, and posterior scapular arteries, were seen to radiate from this point.

It is now *two years and a-half* since the operation was performed, and the cure appears to be complete. The artery has not acquired any increased degree of calibre, and it requires excessive pressure with the finger to discover any trace of the old sac.

This, it must be confessed, is a brilliant success, and the fact, now indisputably proved, that electricity coagulates the blood in the living artery, may lead to further applications; but we must not conclude, from a few successful cases, that the new agent is to throw into the shade the discovery of Hunter. Even from the confession of M. Abeille, the pain occasioned by electro-puncture, in cases of this kind, is of so violent and distressing a nature, that the usual operation of ligature is preferable in all cases where it can be applied, as in aneurism of the femoral artery, &c. Besides, the accidents which may attend electro-puncture are fully equal to, if not greater than those of ligature,—hæmorrhage, cauterization of the sac or skin, inflammation and suppuration of the sac, &c.

I should not omit to mention, in reference to the above, that M. Abeille has performed ten experiments on dogs and sheep for the purpose of ascertaining whether the blood can be coagulated in a healthy vessel by means of electricity. In all the experiments the artery submitted to the action of electricity became plugged by a firm coagulum in a few minutes.

TREATMENT OF PHTHISIS.

M. Lecouppey flatters himself that he has succeeded in discovering a cure for this *opprobrium medicorum*. The following extract from a note which he read at the last meeting of the Institute shows that his method is at least simple, if not certain. "Everybody knows that the first period of phthisis is almost inevitably followed by the second; and the latter by death, if we abandon the disease to itself, or, what is nearly tantamount, treat it in the usual manner. Yet we possess a preparation which is capable of arresting the progress of tuberculization and even dissipating this condition completely. The preparation to which I allude is the common mercurial ointment. I administer it internally, and in the form of a pill, in the dose of 40 to 50 centigrammes a day, half in the morning, the other half at night.

Under the influence of this treatment, when employed in the first period of consumption, the symptoms soon decline, and some of them disappear in an order which is constant. Thus, when hæmoptysis exists, it is the first symptom to disappear; next, the evening sweats; after them the cough declines; finally, the lesions indicated by stethoscopic signs gradually yield, and a cure is often obtained in a few months. Such, at least, is the result of extensive experiments which I have made, and I have no hesitation in affirming, that the same results will be obtained by all those who may choose to repeat my experiments."

The above, you see, puts naphtha and the other "infallibles" completely out of joint. Before, however, we take the assertions of the Author for Gospel, it may be well to await the report which has been entrusted to Majendie, Andral, and Rayer.

The remedy of M. Lecouppey is an old one. For something new I must refer you to M. Bonnafont, who has conceived the ingenious idea of "gaseous injections." At first M. Bonnafont intended to apply these injections to diseases of the ear (the idea may be useful to some of our auricular quacks), but, unfortunately, patients were wanting. He, therefore, deferred his project until a soldier came under his hands with hydrocele. Immediately the apparatus was prepared—100 grammes of water and of ammonia, and a double pump to force in the gas. As soon as the fluid was evacuated from the scrotum, an assistant set vigorously to work, and pumped in the ammoniacal exhalations, until the scrotum had acquired the same volume as before the operation. The aerial injection was allowed to remain thirty-nine to forty seconds in the bag. The gas was then pressed out, and, as the patient experienced no pain whatever, the operation was repeated.

During the first three days the scrotum was completely free from pain or redness; for the next three some redness, with slight tumefaction and heat, manifested itself. On touching the scrotum a little fluid was discovered in its cavity. On the 12th day all heat and redness had disappeared, and in two months the patient was perfectly cured

SCOTLAND.

[From our Edinburgh Correspondent.]

We begin to feel that the crisis of Medical Reform is not far distant, and it may not be without its use if we give the opinions generally entertained here on the subject. Sir George Grey has announced, that the proposed Bill is nearly complete; and it is understood that, if no unexpected obstacle start up in the meantime, it will be introduced early next session. Without pretending to the gift of prophecy, or to seeing further into a millstone than our neighbours, we are nearly of one mind here that, when next session comes round, the chance of Medical Reform, for our day, will rest on this one cast more. If, owing to new dissensions among the parties whose benefit is more or less directly purposed, the Bill shall either not be introduced, or, after being introduced, shall miscarry, we make sure that the existing race of statesmen will be cured of the ambition to harmonise the discordant elements composing the Medical Profession. The question, then, which should at this moment press on every Medical Institution, on every Medical circle, on every individual Medical man, is,—Shall we cast away this last chance of Medical Reform rather than sacrifice our own particular objects? We take it for granted, that any reasonable measure of Medical Reform, any such measure as can possibly be laid before Parliament next session, though it may not satisfy the wishes of all, must have for its effect the elevation of the character of the Medical Profession throughout the United Kingdom, and the increase of its efficiency as respects the interests of the public. These are advantages worth some price. Some sacrifice of corporate or individual feeling,—and more than feeling it can hardly be,—should not be grudged for the general good, as well of the Profession as of the public. By the system of registration and the establishment of uniformity of education, as excluding the rivalry of imperfectly-qualified Practitioners, every man in practice will immediately benefit. Compared with this gain, how trivial is the disadvantage of a small infringement of any corporate rights? Were we not assured of the fact, it would hardly be credible, that the chief obstacles to Reform have lain with our principal Medical Institutions,—our Royal Colleges, Medical Companies, and the Universities. Surely, it cannot be otherwise than by shutting their eyes to everything beyond their own walls that the individual members of such of those bodies as throw impediments in the way, can justify their conduct to themselves. Of the honesty and uprightness of their intentions not the shadow of a doubt may be entertained; but of the clearness of their moral perceptions, there occasionally lacks proof. They may use the argument that they do no more than practise the immemorial usage of Corporate Bodies when they resist even the appearance of encroachment on the rights in their possession. But if it can be shown that they hold these rights merely in trust for the general good, that these were originally conferred, not to serve private interests, but to invest certain parties, supposed by their position to be disinterested, with power and authority to be employed expressly for the public advantage, then they are bound to satisfy us, not merely that they are acting in the corporate spirit, but that that corporate spirit, in this instance, realizes the end and purpose of their charter. But if there be one thing more certain than another it is, that all our Royal Colleges and Medical Companies, as well as our Universities, exist not for the benefit of the individuals composing them, but for the common good. The restraints which their privileges impose on public freedom are not real grievances, as long as these restraints yield greater public benefits. But it is never to be forgotten, that these restraints are not good in themselves but only by their effects, and no longer than these effects are produced. And when these interfere with the original end in view, the holders of such privileges do not act a conscientious part, when they resist rational reform, merely because it may diminish their personal consequence. If the impending change involve pecuniary sacrifices, they are entitled to ask, and, of course will obtain compensation.

Of the Bodies likely to be affected by the enactments of the forthcoming Bill, some are more or less open, others more or less close corporations. Of the Royal Colleges, the London College of Surgeons is the very type of a close corporation, limited to a small fixed number of Life-Fellows, self-elective, inaccessible to the members of their own body by any means within their own power; and this character it must still retain, notwithstanding the operation of the new Charter, till the Life Fellows become a decided minority. The London College of Physicians, though perhaps as often held to be a close corporation, is close in a very different sense from the College of Surgeons. It is unlimited in number, and it is in the power of every young man of ordinary means, capacity, and respectability, so to direct his studies as to secure his admission into the College, as a Fellow. If it be inconvenient for him to study at

Oxford or Cambridge, he may study at Dublin and yet take his degree at Oxford. Even the signing of the Thirty-nine Articles, in as far as it is requisite, can hardly be said to make the College a close corporation in a country where episcopacy is the prevailing religion. The other Royal Colleges, those of Ireland and Scotland are open to a greater extent—that is, the Fellows are unlimited in number, and by a certain course of education, admission is open to all. Even the Universities are hardly close bodies, when the old constitution of the London College of Surgeons, or what is still its actual constitution, is made the standard.

In the absence of all positive information as to the quarter where lay the chief opposition to the progress of reform during the two last sessions, the Profession is entitled to consider, on general grounds, what weight should attach severally to the opposition of these Corporate Bodies. If the London College of Physicians resist Medical Reform, we may expect, by reasoning with them, to overcome their prejudices; and the same thing is true of the other Medical Bodies of the United Kingdom, whose numbers are supplied from the ranks of the Profession at large. We have no wish that the event should justify our argument; but it is not the less necessary that it should be entered on. As it is a rule which hardly fails, that the more close a Corporation is, and the fewer the number of its members, the more tenacious is it of its privileges, the London College of Surgeons can hardly escape the suspicion of having offered the greatest and the least consistent opposition. And if the remnant of the twenty-one Fellows who once composed the College of Surgeons, and still constitute the majority, having no common tie with the rest of the Profession, oppose themselves to measures of improvement, we can expect no argument to bear on their prepossessions. Estimable as they are individually, and deservedly high as they stand in surgical reputation, their opinions, when adverse to those of the Profession at large, should have no weight. The constitution of this Body under the old system, by which their habits of thinking have been formed, was such as absolutely to preclude their opinion on the proper organisation of the Profession from being just—it is hardly conceivable that, consistently with human nature, they should not see any means proposed for the general elevation of the condition and character of Medical practitioners through a false medium. Whatever raises the general practitioner diminishes the distance of rank between him and them. What we insist on, then, is that their opinion, if opposed to the sensible part of the profession, should have no weight with the Legislature; it should be overruled. Perhaps we wrong the College; and, if so, we shall not be slow to express our regret; for, while we express so much distrust of the present Corporation as represented by the Council, we are far from joining with those who wholly condemn the late Charter. We think it extremely probable, that, as soon as the life members in the Council become a decided minority, that body will come to be really and efficiently representative of the wishes and interests of the most respectable portions of the Profession. We must not forget that the self-election has already ceased, that the number of the electors is unlimited, that the privilege of voting is free to all who choose to qualify themselves by the requisite education and examination, and that the period of a councillor's continuance in office, unless re-elected, will not exceed eight years, so that all that constitutes the peculiar closeness of the Council up to this time will finally disappear. Thus a great reform is in progress of being worked out in the London College of Surgeons; and what we wish to see is a like measure of reform put in motion as respects the Profession at large.

Appointments.—On the recent visit of Her Majesty to Ireland, Sir James Clark, who accompanied the Royal party, was elected an Honorary Fellow of the Royal College of Physicians of Ireland.

TO SUBSCRIBERS.

Subscribers in want of any of the back Numbers are recommended to complete their sets. Cases for binding the volumes, price 2s. each, are now ready for delivery.

New Subscribers will oblige by forwarding their Names direct to the Office, 147, *Strand, or to the News Agents or Booksellers. All Post-office Orders should be made payable to the Publishers,* Wm. S. Orr and Co.

THE MEDICAL TIMES.

SATURDAY, AUGUST 18, 1849.

In the north of England, a numerous sect of Medical heretics exists, familiarly known by the name of "Coffinites," and the drug which these self-constituted doctors employ is the lobelia inflata, which they administer to their patients in heroic doses. Some of these Coffinites have had the misfortune to be charged with the crime of manslaughter, in consequence of persons having entertained the idea, that, instead of curing, they have killed their patients.

At the Cumberland Assizes, about a fortnight since, a young man, named John Wood, was charged with the manslaughter of Thomas Wilson, at Maryport, "by administering to the deceased a certain drug called lobelia, from the effects of which he died." He had been subject to occasional attacks of peritonitis; and, on the 12th of last April, he was again seized with this peculiar inflammation. On the 15th, he became so ill, that Mr. Wood was sent for, who, on his arrival, prescribed an injection of a teaspoonful of lobelia inflata, with other ingredients. He also ordered an emetic composed of a teaspoonful of the lobelia, and in two hours after repeated the doses. It appears that a teaspoonful is equivalent to about sixty grains of the drug, so that the emetics contained together about 120 grains, and the injections the same quantity. After these *remedies*, the patient became worse, and Dr. Pearson and Mr. Curtis were summoned to attend him. He, however, gradually sank, and died in the afternoon of the same day. At the trial of the prisoner, these two Medical gentlemen were called as witnesses, and stated it as their opinion, that the death of the patient was hastened by the lobelia. Mr. Serjeant Wilkins, who defended the prisoner, not only subjected the Medical witnesses to a severe cross-examination, but, in his address to the jury, uttered, we are told, "a sweeping condemnation of the whole Medical Profession." He said that he was once a pupil of the celebrated Mr. Abernethy, who was wont to assert, that "doctors killed more than they cured." The learned counsel, moreover, commented on the notorious disagreements between Medical men on almost every matter connected with the practice of physic, and stigmatized them as more narrow-minded and jealous than any other class of men.

The interest of this trial is connected chiefly with the speech of this learned Serjeant to the jury, in order to obtain a verdict in favour of his client. The law has wisely and humanely allowed the privilege of counsel to those who stand charged with infraction of the laws. This has been done to aid the cause of justice; and it was never intended that hired advocates should, in the exercise of their calling, attack individual character, or denounce a class of men who are, from the nature of their Profession, frequently called to give evidence in courts of law against individuals charged with crimes. Medical witnesses, in presenting scientific testimony before judicial tribunals, appear as the great defenders of the morality of society. They have to speak, as science herself shall dictate, truths which have been revealed to them by a rigid process of investigation, and which no "golden bribe" can induce them to withhold. The medical witness discharges his duty, very frequently, at a great pecuniary loss to himself. To detect crime, he has often to institute expensive chemical analyses; and then, at the assizes, to journey to some distant town, where he is kept for days away from his home, without anything like adequate remuneration. The stern morality of the Medical Profession is nowhere better displayed than in our Courts of Justice; and we hesitate not to say, that the security and advancement of society depend greatly on it.

And this Profession, Mr. Serjeant Wilkins has thought proper to denounce. He doubtless considered himself highly competent to pass a judgment, because he was once a pupil of Mr. Abernethy. Surely the mantle of the Surgeon has not fallen upon the shoulders of the Lawyer. If so, let him, prior to his becoming the advocate of self-constituted doctors, arraigned upon the charge of *mala praxis*, follow his revered master's advice, and take some blue pill to clear away the bile.

We deny that Medical Men notoriously disagree on almost everything connected with the practice of physic, and that they are more narrow-minded and jealous than any other class of men. There are great truths in medicine upon which all are agreed, and in the treatment of diseases there are certain fixed scientific principles to which all bow; diversity of practice, therefore, does not warrant the assertion, that Medical Men disagree on almost every matter connected with the practice of physic. Neither is it true that they are more narrow-minded and jealous than any other class of men. That they have their failings we acknowledge; and that the many different kinds of medical diplomas existing in this country have produced a strife about superiority, we also confess; but we think that as much jealousy exists amongst the members of the legal profession as the Medical; and we are quite sure that the calibre of the minds of the latter is as large as that of the former, our Courts of Justice themselves being judges.

But what must be the effect of Mr. Serjeant Wilkins's statement upon the public in the immediate neighbourhood where it was made? Here a peculiar species of quackery is rife. Men ignorant of the first principles of medical science dare, with a single nostrum, to treat the most formidable diseases. The advocate's sneer at legitimate medicine will encourage them in their dangerous work, while the poor and unlettered multitude will have greater faith than ever in nostrum-mongers, and increasingly become their victims. Surely legitimate medicine, with

all its imperfections, is better than quackery. Why, then, should hired advocates be permitted in Courts of Justice to make unjust attacks upon our Profession? Counsel ought not to be allowed quite so much liberty of speech in defending their clients.

THE CHLOROFORM CONTROVERSY.

When the last month of the year 1846 commenced, Anæsthesia was still an obscure and little known term in Medical nomenclature. But revolutions were then at hand in Medicine as well as in the political world, and now no household word is more familiar in our mouth than the so-lately slighted Anæsthesia. No longer ago than the end of the year 1847 Peroxide of Formyle was a sound to startle an Examiner at the Hall from his propriety now ladies lisp its synonyme Chloroform at tea-tables, and unless they are belied, even inhale it round the circle as a part of the evening's amusement. We can hardly join in approval of such experiments as an ordinary pastime for ladies. But, as long as the knowledge of the effects of Chloroform is still short of complete, and feelings of timidity interfere with its employment in proper circumstances, instead of blaming those of either sex who have courage enough to make themselves the subjects of experiment, we should confess that they lay us under no slight obligation, by turning their natural gifts to the benefit of mankind. We should not forget, that to the courage of a distinguished lady, the last century owed the introduction of small-pox inoculation.

To Chloroform we confine our remarks at present, because we think it would be still premature to discuss the whole subject of anæsthetic agents, notwithstanding the copious materials supplied to us for that purpose in Mr. Nunneley's late elaborate paper in the Transactions of the Provincial Medical and Surgical Association.

All great discoveries necessarily encounter opposition, the reason obviously being, that a discovery is hardly great which does not make inroads upon established opinions and modes of thinking. But there are pseudo-discoveries dazzling with a false brilliancy, against which all sensible people must finally set their faces. How, then, are we to discriminate between opposition to captivating errors, and efforts to stem the progress of discovery because the new truth disturbs or displaces favourite usages or opinions? One answer there is, and little more—the words of the old adage, "*Magna est veritas et prævalebit.*" Something one might expect to gather from the characters of the men who take different sides in such a controversy. But this test will be more easy hereafter than it is at present. When a question turns on the introduction of a novelty in practice which is not the legitimate sequel of principles before recognized, we may expect many persons of the soundest practical sense to rank at first among its opponents. But what chiefly interferes with the utility of the test in question, is the facility with which, in a publishing age like the present, many incompetent people, without leave asked or given, may set themselves up for champions, and damage the cause they adopt. That a man may write a book to serve the cause of his adversary, was already known in the primitive age of the Patriarch Job; and we cannot but think that some of the pamphlets against Chloroform are such books as Job wished his adversary would write. Were we hostile to the introduction of Anæsthetic agents, we should sometimes be forced to cry out, "Save us from our friends!"

But to pass from this class of opponents. Of those who really deserve attention, Dr. Meigs is one of the most formidable; and he is formidable, less by what he says than by the simple circumstance of his being an opponent, while he is a Physician of unquestionable good sense. He is not satisfied with the *prima facie* of the case in behalf of chloroform; he declines to engage in the inquiry himself; he waits till the cumulative experience of others determines the question one way or other. We cannot blame him. He sits, like a cautious judge on the bench, his mind made up not to commit himself till the pleadings on both sides are exhausted. Dr. Tyler Smith is an opponent of less weight than we might expect from his reputation. His lecture on Etherization, in the spring of 1847, has been the rallying point of a little knot of combatants against anæsthetics but the lecture was premature, the proper use of speculative views being, not to weigh facts, but either to suggest new sources of research or to find a principle of connexion among already established facts, so as to secure them against the love of change and the detrimental influence of fashion and cavil. Dr. Samuel Ashwell confounds the use of chloroform in labour with meddlesome midwifery, and so betrays a greater earnestness to find an argument against the practice than to see clearly the true position of the point at issue. Dr. Radford sees nothing but evil in anæsthetic agents. Dr. Merriman, Dr. Montgomery, Baron Dubois, Dr. Snow, and a long catalogue besides, subscribe to the utility of anæsthesia in Surgery, while they limit its employment in midwifery to obstetric operations, "such," says Dr. Montgomery, "as instrumental delivery, turning a child in utero, or the removal of a retained placenta." These, then, occupy the cross-benches.

On the other side, Dr. Simpson concentrates in himself the championship in behalf of chloroform. He acts and speaks like one truly in earnest. His convictions are like the instinctive grasping of a truth which sometimes precedes its development by the regular forms of evidence. His impatience cannot brook the tedious stages of the ordeal through which discoveries commonly fight their way to general reception. His tactics are to expedite the process—to hurry us through all our doubts, delays, and difficulties, without giving our indolence time for a single yawn. So far all is well. But the question is natural—Are we safe in his hands? Some hold certainly we have upon him. He has a reputation to lose. If chloroform in the practice of midwifery be finally condemned, his credit with the Profession, and even with the public, will suffer some discount. Moreover, his talents, and in particular, the penetration and research which originally gave him his reputation, must go for something in the estimate.

But we must hasten beyond these preliminaries. These but prepare the way for the main body of the proof, which can lie only in authenticated facts.

As regards surgical operations, the use of chloroform is quietly settling down into an established practice. If any man still doubts, let him but repair to some Hospital, where the benefit of anæsthesia is afforded to the patients, and we recommend him, if possible, to choose a day when lithotomy is to be the operation. If he has been accustomed to see that operation performed in the usual manner, we assure him beforehand his doubts are destined to undergo a severe ordeal, when he comes to remark what a change chloroform works, both as respects the patient and the surgeon. When he sees the patient, freed from apprehension, still and motionless as in a profound sleep, the perineum like no perineum that he ever saw before—not like that of a statue, not like that of a subject in the dissecting room—but the perineum of a living and breathing man, destitute of sensibility, yet with all the prominence, elasticity, and warmth of life, presenting itself to the knife, to be divided with all the nicety which the unembarrassed tact of the operator can command; and when he sees the surgeon engaging in this once so unmanning task, with a conviction that he is inflicting no pain, and not raising even the thought of danger, however naturally timid the patient may be—when he discovers, that the qualities required for lithotomy are no longer the rare gifts of nerve, coolness, and self-possession, but are reduced to what so few Hospital Surgeons now fail in, namely, anatomical skill and manual dexterity—unless his heart be harder than the nether mill-stone, we think he will ask no further proof, that surgery has acquired a new means of affording relief to suffering humanity.

To come to the same agent in Midwifery,—the real question has to be disencumbered of a quantity of tag-rag unnecessarily pinned on it by either party. The dispute is to be settled solely on obstetric grounds. Theological objections are childish in the extreme—the immodest ideas excited by it, who will believe? Again, is the value of the practice proved by the opposition offered to it, any more than the like opposition tells in favour of Homœopathy? Or must we give in to it, because traces of the same practice are discoverable in the most ancient times? All these topics obscure the real question at issue.

The first point to be settled is, the question of safety. Is it a safe practice? It is more than a year since Dr. Simpson produced a series of Reports from a score of accoucheurs in different parts of Britain, referring to little short of a thousand deliveries in which chloroform had been used, with the effect of convincing the reporters, not merely of its being free from danger, but of its suitableness to avert many of the evils attendant on parturition. Dr. Murphy is hardly less strong in behalf of its safety than Dr. Simpson and his correspondents. And how many more testimonies might be produced now in its favour to the same effect! No doubt it is capable of destroying life, and Mr. Nunneley, in the paper already referred to, has clearly shown how readily it may produce that consequence. But to men in the daily habit of using opium,

conium, hydrocyanic acid, belladonna, and the like, this is an argument of small avail. If an unbiased judgment on this point be, that, in careful hands, it is as safe as the use of the narcotics of daily use in the practice of medicine, any further opposition from a supposed danger attending the anæsthetic state in parturition is but a waste of time.

A second point at issue is, whether the use of chloroform interferes in any respect with the appointed actions by which parturition is effected. Here some discrepancy of statement occurs as to the facts. Dr. Snow objects to chloroform in ordinary parturition, apparently because he thinks it retards uterine action; yet with this limitation, that, in rigidity of the os uteri, and in an unyielding state of the perineum, it shortens the duration of labour very much by relaxing these parts. But, in opposition to what he affirms, we have a host of authorities concurring with Dr. Simpson, that there is no interference, or at least none in any part of the process which is not more than compensated for by the aid afforded in subsequent stages. Dr. Murphy says, "it does not interfere with the action of the uterus, unless it be given in very large does, which is never necessary." Dr. Malcolm says, he has never seen the uterine contractions arrested by its use, though he has no doubt a large dose would have that effect; and Dr. Moir thinks that, in some cases, when chloroform is freely administered, it may retard the pains a little, and may even lessen their power; but, while he expresses this doubtfully, he says he is quite satisfied that "the second stage is much accelerated, especially towards its termination, by the chloroform doing away with the resistance offered to the expulsion of the head by the muscles at the outlet of the pelvis." Here the opponents of chloroform in ordinary labour fight at a disadvantage, repelling observation with assumption; for, as they do not employ chloroform in these circumstances, they have no opportunity of ascertaining whether it does or does not check the natural progress of parturition. Unless, then, cause can be shown why the powers of observation, or the good faith of the promoters of chloroform in natural labour, should be distrusted, this point must be held to be settled on the side of chloroform.

Much has been said against the abolition of pain in parturition, on the ground that pain is physiologically an element in the natural process. Our first impulse here is to ask, if this be sense or nonsense. How far, then, is it sense? It is undeniable that pain in general is a physiological element—that important ends are served by pain in the animal economy. And, doubtless, by the pains of parturition, some essential purposes were designed originally to be fulfilled; without the attendant pains, for example, a woman might be delivered in sleep in a manner fatal to her offspring. In ruder times, but for the pains and cries of childbirth, a woman might not have been usually afforded that sympathy and aid so little short of indispensable to her own safety and the preservation of the infant. But in the social state as it exists among us, who shall say that pain may not have ceased to be an essential physiological condition of parturition? At all events, the only legitimate use of the admitted principle, that pain is an original physiological element in parturition, is to suggest an objection to the abolition of pain in the process. But to render that objection of effect, it must appear by observation that the abolition of pain, under present circumstances, renders the process less adequate to its proper ends than when the natural pains are allowed to take their course. But we have seen that there is the best reason to think that chloroform does not interfere with the appointed acts by which parturition is effected, and it is therefore established that the process can take place in full perfection, independently of the perception of pain. Under this head, then, the question is again decided in favour of chloroform.

If this last point require any further illustration, we would remind our readers that the physiological state of mankind is not stationary, like that of the rest of the animal kingdom, but progressive, and that pains and pleasures multiply, apparently in opposition to the original laws applicable to the race. But, surely, no one will seriously maintain that man's development as a social being, by which a thousand modifications are produced on the original condition in which the earth at first received him, is not as much the work of the Author of his being as is the onward progress of his bodily frame from a hardly visible germ to the full perfection of its actions in adult age.

To discuss, as a separate subject, the use of chloroform in obstetric operations, is no longer necessary. As a principle it is hardly disputed; and it shares in the general consent to employ this agent, as an invaluable aid, in the painful operations of Surgery.

But to sum up our statement—the determination of right or wrong in the employment of anæsthesia during natural labour is not to be founded in the last resort on *à priori* arguments—it plainly becomes narrowed to one or two simple questions of fact; namely, Is the prolonged use of chloroform sufficiently safe? and, Is it proved that the effect of this agent does not injuriously interfere with the natural acts on which parturition depends? These two questions we feel warranted, by the consideration now given to the subject, to answer in the affirmative.

ON THE SUPPLY OF WATER TO THE CITIES OF THE AMERICAN UNION.

The subject of employing leaden service-pipes for the introduction of water into some of the great cities of the United States, has lately occupied the attention of a Board of Physicians and Surgeons of Boston. The inhabitants of this place are about to be supplied with water from the Cochitnale Lake, and as the water of certain wells was found to act rapidly on lead exposed to its influence, it became a matter of importance to see what would be the effect of the water of the lake on that metal.

The investigations of the American Physicians will be interesting to the English Medical Profession, from the circumstance of a recent serious illness having afflicted the illustrious exiles at Claremont, and also from the fact, that in some other localities families have suffered from peculiar symptoms, which have been ultimately found to result from the drinking of water impregnated with lead.

The Municipal authorities of Boston appointed a Board of Consulting Physicians to report to the City Council on the materials most entitled to preference for water pipes, and Professor Horsford, of Harvard University, instituted a series of experiments, which, with "a great mass of evidence, derived from very extensive observation of the use of leaden pipes for a long series of years," have led to most important conclusions.

From a Report of the Water Commissioners, we learn that they were compelled to begin the work of laying down the distribution pipes, while the eminent physicians and chemists were prosecuting their investigation. As they had not made known their opinion, it was deemed improper to make use of a material which might in the result be proscribed as dangerous to the health of the citizens. Iron pipes, therefore, of one and a half and two inches in diameter, were laid down for carrying the water from the street mains to the side walks, and in part to the dwelling-houses. The cost of these tubes was considerably higher than those of lead, and in laying them down it was found that they were more liable to be broken. In the meantime a variety of experiments were instituted upon tubes constructed of other kinds of materials, and we will briefly place the results before our readers. In those made of block tin it was found that some waters gradually dissolved the metal; and that the decomposition did not cease in a short time like that of lead under the same circumstances, but continues indefinitely as far as any experiment has been made. Tin is also liable to rapid decomposition by being brought into contact externally with certain acids and gases, to which in various positions it may be exposed. The question, whether these changes which the metal undergoes produce any deleterious effect on the water, has not been satisfactorily answered.

Pipes of malleable iron were found soon to corrode, and the rust not only rendered the water unfit for use in the washing of linen, but in process of time it closed the apertures of the pipes.

Tubes of sheet iron, coated internally with hydraulic cement, promised to be highly useful under certain circumstances. The cement served the double purpose of giving additional strength to the pipes, and of preserving them from rust when exposed to moisture. One great impediment, however, to the employment of the coated iron will be the expensiveness of the materials.

According to the "Report," the Consulting Physicians have not thought proper to recommend distribution pipes, composed of lead, till further experiments had been made. It was desirable to reconcile the fact, that lead immersed in water taken from the Jairmont, Croton, and Jamaica Pond water-works, undergoes a perceptible partial dissolution, with the well-attested evidence that the inhabitants of Philadelphia, New York, and Boston, were constantly using these waters, drawn through leaden pipes, without injury. Professor Horsford, after a most searching investigation, has

arrived at the conclusion that the action of the comparatively pure water of lakes and rivers upon bright bars of lead, which on their immersion in it is distinctly perceptible, ceases after a few days, and that the coating thus formed remains unchanged for a long period. Not a trace of lead has been detected in water which has passed through tubes thus affected. The Professor, however, states, that when nitrates are found in water, it always acts more energetically upon lead, and that the unequal proportion of these salts constitutes the chief distinction between different waters in their relation to the metal. Wells and springs so situated as to be replenished by the filtration of water through a soil enriched from the stable, or by the wash from collections of animal substances, nearly always contain nitrates. The water having been in contact with lead, becomes dangerous to the health of those who drink it, or use it in the preparation of their food. This will account for the fact that the water of wells situated—as are a large portion of those in towns and cities, and of springs located—in the midst of richly cultivated fields, or in the vicinity of animal deposits of any description, will produce the chemical effects here referred to, while the waters of rivers not particularly exposed to contact with substances of that nature will be destitute of any such power.

By making known the researches of our American brethren we may, perhaps, be doing some service to the inhabitants of this great metropolis. Hitherto the Thames water has not acted to any extent upon the leaden pipes by which it is conveyed to the houses. The animal matters, however, which are conveyed into this river are continually augmenting; not only polluting the water, but making it more capable of forming those salts of lead which will certainly prove highly injurious. Our daily contemporary the *Times* will, we hope, make use of this fact in its future efforts to prevent the *excreta* of London being poured into the Thames.

DISTRICT LUNATIC ASYLUMS IN IRELAND.

We had hoped, that it might not have been necessary for us to recur to the above-named Charities, unless in terms of praise at the amended regulations and the reforms promised in the last report by the Government Inspectors. These regulations and reforms are not yet forthcoming; nor, we fear, is it likely that the appointment of *resident* Medical Superintendents, with strictly and clearly defined rules for the performance of their duties *as such*, will take place until we again apply the test of public opinion to the details of the present absurd and paralyzed system. The statement that medical gentlemen are, as vacancies occur, nominated by Government to the office of Resident Managers, while *by rules of Government still in full operation* to prevent them, unless by an open violation of these rules, to administer the slightest medical aid to an inmate of their Asylum, is too frivolous a defence to stand for a moment the test of humanity and intelligence. In the kindest and best spirit we call upon the two Commissioners who preside in Ireland over this great branch of the Profession, to enter at once and fearlessly on the real and substantial fulfilment of their promise to the public and to their brethren. They owe it to themselves and to their high position to do so; and, in after years, the gratification they will assuredly feel, when reflecting on the benefits they were instrumental in conferring, not only on the Insane, but on the Profession in Ireland, may more than counterbalance any ephemeral and interested adulation they now possibly receive, from the few who gain by the existing condition of the District Lunatic Asylums of that unfortunate country.

DR. SEYMOUR AND DR. CHAMBERS.

We have hitherto refrained from noticing the disgraceful controversy between Dr. Seymour and Dr. Chambers—disgraceful alike to the anonymous and foul writers of the scandalous letters, to the person ignominiously branded as their Author, and —we would almost say still more—to those who, upon any proof short of actual demonstration, brought the cruel and the loathsome charge.

Reluctant as we confess ourselves to sully our pages with this meretricious subject, and determined as we are to take no part in what we conceive to be as distasteful to the great body of our readers as unfit for the pages of a Journal such as the *Medical Times* professes to be, we feel, nevertheless, called upon to publish the following letter from Dr. Seymour chiefly because, without going into any details of the circumstances, he denies, in language which cannot be misunderstood, the imputations thrown upon him. In giving insertion to the letter, we beg to remind both the parties more immediately concerned, that while the quality of mercy is twice blessed in blessing him that gives and him that takes, scandal and calumny are doubly cursed; and, like the discharges of the beastly yahoo from its unhallowed tree, though they may miss the passing traveller, they never fail to bespatter the filthy thing itself.

[To the Editor of the Medical Times.]

SIR,—As Dr. Chambers has addressed a letter to the *Lancet*, of the 11th inst., maintaining, that he possesses proofs (without stating them) that his *ex parte* assertions in the *Lancet*, of the 9th of June, relative to certain anonymous letters, are true, and thereby, contrary to his own acknowledgment in writing, imputes to me some knowledge of the base and stupid anonymous letters received by him in June, 1848, and the suspicion carefully concealed from me until March 30, 1849, while he whispered the calumny to others; and wishing to make my solemn denial as public as possible, I request you will insert this declaration in the next number of your Journal.

Upon my faith as a Christian, and my word of honour as a gentleman, I never had anything whatever, either directly or indirectly, to do with any anonymous letters addressed to Dr. Chambers, or to any other person. With regard to all other allegations, I adhere to my statement of the 9th of June.

As to Dr. Chambers's declaration of his readiness to produce the proofs of his statements; I have only to observe, that his not having done so long ago was no fault of mine, and I can assure him that they should long since have been before the public, if he or his friends had ever given me the opportunity (anxiously wished for) of compelling their production in open Court.

On the contrary, instead of publishing his *ex-parte* proofs, Dr. Chambers and his friends first acknowledge, both in writing and most unequivocally in speech, their utter disbelief of my being connected with the anonymous letters, while they sustain the accusation by insinuation.

I join with Dr. Chambers in the expression of regret contained in his letter to the *Lancet*, that a matter of this nature should so long have engaged the attention of a liberal Profession; and I will go a step further, and express my sorrow that I, a member of that Profession, only desirous of discharging its anxious duties in tranquillity and good faith, should, behind my back, have been made the object of secret inquiries and calumnious imputations by those who were my professional colleagues, and whom I had, through a series of years, considered as my private friends.

I am, Sir, your obedient servant,
EDWARD J. SEYMOUR, M.D.

August 13, 1849.

THE OPERATIVE SURGERY OF JOHANN FRIEDRICH DIEFFENBACH.

Edited by
J. STEVENSON BUSHNAN, M.D.,
Fellow of the College of Physicians, Edinburgh;
And
ALEXANDER URE, Esq.,
Fellow of the College of Surgeons of England, and Surgeon to the Westminster General Dispensary, &c.

(Continued from page 125.)

CHAPTER II.

(Sutures continued.)

III. THE SUBCUTANEOUS, OR LACED SUTURE.

This is peculiar, in so far as it lies under the skin. All other sutures transfix the edges of the wound, and bring them into contact; but, in the subcutaneous, the thread runs in a circular manner, at some distance from the wound or fistula beneath the skin, round the aperture, which it embraces, like the ligature of an artery. It bears, accordingly, no affinity to the preceding varieties of suture, inasmuch as it encircles the gap merely at a remote point, and laces it in from the centre.

The execution is more difficult than with stitches, as generally applied to recent wounds, having the form of a cleft or a flap. Here, on the contrary, it is resorted to in round preternatural apertures, invested with cuticle, which have been eroded, cauterised, incised, or excised, and sundry inlets and outlets of the body. The procedure is as follows; —A puncture is made through the skin with a strong curved threaded needle, held laterally anterior to the eye, in the forceps used for that purpose, at some distance from the opening meant to be closed, and of which the edges have been previously inflamed with caustic or pared level. The needle is next carried under the corium into the cellular texture, always observing the same relative distance from the aperture, in such wise that a sweep of a quarter or a third of a circle is described. The point is then directed upwards, passed through the skin from within outwards, and drawn together with the thread some inches externally. The needle afterwards returned through the same opening beneath the skin, made to describe another quarter circle, emerge from beneath, and to pass a third or fourth time beneath the integument, until the whole aperture is engirt with the thread at one uniform distance. The needle is finally brought out again at the original puncture, and, with the thread hanging a finger's-length out of the aperture, together with that still remaining in the eye of the needle, the constriction of the aperture is to be effected. If the opening be small, and the thread convenient, it is tied with a couple of knots, but not so firmly as during the ligation of a large artery. The knot rests upon the puncture, and generally drops into the little pit in the skin. Hereupon the ends are shortened, and the margins if torpid, pencilled over with tincture of cantharides, otherwise bound with strips of plaster, to favour the process of subcutaneous conglutination, and to exclude air from the punctures.

In large openings and fistulæ intended for closure, as in the instance of artificial anus, where the finger can be introduced, the same mode of ligature is adopted, but on a greater scale. For a narrow urinary fistula, I take a common thread and a fine curved needle, and puncture not further than two lines from the edge. I then have recourse to one of the largest hafted needles, armed with a hank, consisting of from four to eight strong waxed silken threads, and carry this round the orifice at an inch apart from it, until the thread is again brought out

with the needle at the original puncture. To prevent untimely division of the soft parts which might interfere with union, it is advisable to pull the ends of the thread together sufficiently tight to bring the margins of the opening into moderate contact; a round piece of cork, notched in the middle laterally is placed betwixt both ends of the ligature, a knot made in the groove, and afterwards a loop, which is to be fastened after the interval of a few days, or whenever the ligature has become slack.

Small fistulous openings are sometimes closed by the first suture. The appliance need not be examined until after the lapse of four or five days; if the thread is fast it may be allowed to remain during eight days, and its withdrawal rather deferred than hastened. The same plan is pursued as for the removal of an interrupted suture; the ends of the thread are first put on the stretch, the ring in the enlarged puncture cut through with very fine pointed scissors, and the ligature carefully removed.

In the instance of wide orifices, the suture is tightened every other day, even should closure not have been effected; but great caution must be observed, lest the thread cut its way out before at least a fortnight or three weeks have expired. In the most favourable case, or in one less so, the thread ought not to be meddled with prematurely. Even should it have severed all the intervening textures, there ensues a very considerable diminution of the aperture during the prolonged irritation of the edges and adjunct parts, partly due to the shrinking marginal scar, partly to the subcutaneous coalescence of the parts divided by the thread.

To the employment of this suture I owe many cures in cases which resisted all other means. Its application, indeed, is frequently a troublesome, tedious, and oft-to-be-renewed undertaking; it has, however, this advantage, that each failure is not, as after the evulsion or suppurative disruption of the interrupted or twisted suture, a virtual, but merely a partial one, and conducing, in the long run, to the end in view. The operation ought, therefore, to be repeated until the aperture is quite closed, always going over the same ground as at the beginning. It is particularly suited to salivary fistulæ, urinary fistulæ of the male urethra, vesico-vaginal and recto-vaginal fistulæ, vesico rectal fistulæ, stercoraceous fistulæ and artificial anus. In all likelihood its sphere of usefulness will be yet further extended. Omitting any notice of the quilled suture, the glover's suture, and other antiquated modes of stitching, which have justly fallen into disrepute, the next subject in order is :—

THE UNION OF WOUNDS BY ADHESIVE STRIPS.

All wounds are thus united that are capable of being healed by the first intention, and of which the lips can be retained in contact without apprehension of their breaking open or getting displaced; where likewise the employment of sutures would be superfluous, or else injurious from risk of irritation, as in wounds of the scalp. In the opposite instance, also, where the integument is lax and yielding, or redundant, as after the extirpation of voluminous tumors. In those cases again, where no decided measures need be taken for promoting direct union, or hindering suppuration, as after various amputations. Finally, where a deep formation of pus may be anticipated, and any forcible attempts at knitting the edges by suture would eventually necessitate an opening up of the wound.

The strips of plaster to be applied across the wound after all bleeding has ceased, and the surface been well dried, vary in length and breadth according to its size and the tension of the skin. They are to be supported by transverse strips placed sideways. The assistant is directed to bring the edges accurately together; and to wipe away, with a soft dry cloth, any blood that may remain after previous sponging. The middlemost strips are first laid on, one-half being made to adhere to one side of the wound, and then the other half with gentle pressure to the opposite, in order to keep the edges together. The amount of space between each, is to be regulated by the breadth of the strips. Pressure is to be made, for a few seconds, with a folded towel upon the track, so as to strengthen the adhesion, and get rid of any effused blood. After this, the intervals are to be fitted up by similar strips, until the whole is covered with plaster. Where the skin retracts considerably, the strips hold better when put slantwise athwart the wound, and these duly crossed with others also slanting.

Fine incised wounds of the face and the fingers are best conjoined with court-plaster; of this, a small strip is taken in forceps, dipped in water, so as without removing the glue to render it soft and sticky; one-half is then applied over one side, and, after allowing a moment or so for its adhesion, the remainder is gently pressed down in such wise as to bring the lips into contact. In this manner the requisite number of strips are placed over the whole extent of the incision.

MR. FERGUSSON'S CASE OF MORBUS COXARIUS.

[To the Editor of the Medical Times.]

SIR,—I have no doubt it will interest your surgical readers, to know the present condition of the patient upon whom Mr. Fergusson performed the operation of excision of the head of the femur in January last.

The case is that of the little girl Vigoen, the particulars of which were given at full in Mr. Fergusson's Clinical Lecture, published in your Journal in April.

At that time she left the hospital to go into the country, being able to walk about on crutches.

Seven months having now elapsed since the proceeding was put in force, I yesterday, in company with my intelligent friend, Mr. Hugman, the author of a late work on "Morbus Coxarius," visited the child at her home at Greenwich, and, together with the above-named gentleman, minutely inspected her. The following we found to be her condition :—

The whole length of the extensive cicatrix is in a very firm and healthy state, with the exception of a small portion of the centre, where there is a slight weeping, as one usually sees in scrofulous subjects, after excision of joints, for many months after the operation.

The centre of the thigh, when measured, is as large round as the other. A false joint has formed. *There is perfect flexion and extension of the thigh upon the pelvis.* The power of adduction is considerable,—the power of rotation onwards is slight, as was the case in Mr. White's and Mr. Fergusson's other patients; and, as always must necessarily happen, the insertions of the pyriformis gemelli, and obturators, being cut through. Foot, neither inverted nor everted; whole limb shorter than the other by two inches, although considerably more of the bone was removed.

The patient can plant her toes firmly on the ground, and walk without the assistance of either stick or crutch. Her general health is, in every respect, perfect; she presents, indeed, a happy contrast to the poor miserable creature who was lying crippled in her bed before the operation.

The parents who had, to use their own expression, "beggared themselves in order to get some relief for their child," and who had seen her sufferings so long, are impressed with a sense of deep and lasting gratitude to that distinguished Surgeon, who, by a proceeding creditable alike to his humanity and skill, has brought health, joy, and comfort, where before there was nothing but suffering and despair.

I send this account of the present condition of the patient, not for the purpose of reviving a controversy when evidently there is now no longer any necessity for it, but for the purpose of fairly and honestly laying before the Profession the actual results of this so-much reviled operation, and of showing those of them who are fond of looking forward, and not retrograding, that excision of the head of the femur will be attended with those good results which we expected would follow, when it is undertaken in suitable cases, and with proper care.

But it is more especially for the information of Professor Syme, and those who may agree with him respecting the barbarity and inutility of this operation, that I have taken the trouble to go some miles out of town, and minutely examine this patient. If the learned Professor is one who will be convinced at all, (and I say this with the greatest respect for his high professional character,) he must admit that the results of this case, together with those before published, silently and triumphantly proclaim him a vanquished man, and I sincerely hope, for the credit of Edinburgh surgery, that he will openly retract his written opinions respecting this proceeding, and, even if he does not think fit to do so publicly, it is to be hoped that he will give the pupils of his class, which will re-assemble in the forthcoming session, views respecting this operation totally different from those they have been accustomed to hear propounded.

I may in conclusion state, that the above-mentioned case is the more interesting, inasmuch as before Mr. Fergusson operated, the little patient was under the care of a hospital surgeon, one who ought to be well acquainted with, and able to make use of all the resources of his art, (I could mention his name if I chose, and would fearlessly do so if necessary;) and when it was proposed to him to perform the operation for the relief of the patient, he merely laughed at the proposer of *such an absurdity* as cutting out the head of the thigh-bone in a living human being, with any prospect of safety or advantage.

I remain, yours obediently,
HENRY SMITH.

POOR-LAW MEDICAL APPOINTMENTS.

[To the Editor of the Medical Times.]

SIR,—I often have great pleasure in reading your weekly periodical, and have always found you the strenuous advocate of the Poor-law Medical Officers. There are, however, some points which you appear to have left entirely out of the question.

It is notorious, that the great majority of those officers are young men, who have undertaken duties at a price so low, as precluded the old-established men from conscientiously continuing them without a serious loss. These young men were well aware of the shamefully inadequate terms before they engaged themselves; but the low salaries they hoped to counterbalance by making inroads on their neighbours' business. Why, therefore, do they now complain? Are they disappointed in their expectations? If they made the engagement from ignorance, such could not be the case after a year or two's experience. Again, if they find their duties too onerous for the paltry salary, they had better adopt the example of Mr. Mitchell, of Kennington, and resign their appointments. Be assured, while the guardians can procure men who will undertake the office at low salaries, it would be folly to expect them to give high ones. There is, however, I regret to say, one result of a most serious kind from engaging low-priced medical men, viz., that the poor are most inefficiently and negligently attended. These cheap medical men never think of doing their duty properly, and instead of proper medicines, &c., mutton, beef, brandy, and gin are but too frequently substituted. A long and intimate acquaintance with these matters enables me to speak most positively on this most important subject. Now, it only remains to suggest a plan for remedying many of these evils. It has always been a matter of much regret among the poor that they cannot choose their own doctor; they are obliged to have the one appointed by the Board, whether he is attentive, skilful, or otherwise. Surely some deference ought to be paid to the wishes of these poor creatures, whose comforts are so very limited, and, above all, the poor woman, in the hour of travail, should be allowed to have the medical attendant of her choice. If anything is calculated to allay the sorrows of child-bed, it is the confidence inspired by having her own selected attendant. Why should this boon be denied the wife of the poor man? The following plan, therefore, is proposed as a remedy for several of these evils, and ought to be regularly and uniformly adopted by all Guardians' Boards, and enforced by the order of the Poor-law Commissioner; viz., let every Board of Guardians engage as Medical Officers ALL *the properly qualified medical men* residing in every district, who may be willing to act as such, at a given sum per sick person during the year. That the sum for every such sick person shall be at least 2s. 6d., however long or frequent the illness may be during the current year. That every sick pauper, when he first applies to the relieving officer, or other competent authority, shall receive a "sick ticket," which he may take to one of the medical officers, such as he may choose, and he must be attended by the same medical officer in every succeeding illness during *that* year.

That the medical officers shall be paid at the year's end for as many tickets as they then produce. That the present regulations respecting extras as now exist shall continue, with the exception of midwifery. That for every case of midwifery within one

mile of the medical attendant's residence, shall be paid 10s. 6d. For every case at a greater distance than one mile be 21s.

The above plan should not be confined to the present period of emergency during the existence of the present epidemic; but should continue permanent, and without doubt would obviate many of the inconveniences of the present most unsatisfactory and objectionable system—alike unsatisfactory to the Guardians, rate-payers, medical officers, and poor.

I remain, Sir, yours, &c.,

AGRICOLA.

CONVENTION OF POOR-LAW MEDICAL OFFICERS.—THE POOR-LAW BOARD AND THE GENERAL BOARD OF HEALTH.

[To the Editor of the Medical Times.]

SIR,—The great interest now taken in the subject of Poor-law Medical Reform, leads the Committee to beg the favour of your publishing the following Correspondence:—

(Copy.)

TO THE PRESIDENT OF THE POOR-LAW BOARD.

4th and 5th Wm. IV. c. lxxvi., clause 46:—"And the said Commissioners may, and are hereby *empowered*," &c., &c., "and *when* the said Commissioners may *see occasion*, to REGULATE the AMOUNT of SALARIES PAYABLE to such officers respecting," &c. &c.

10th and 11th Vic., c. cix., clause 10:—"And be it enacted," &c., &c., "that *all* the powers and duties of the Poor-law Commissioners with respect to the administration of relief," &c., &c., "and *all other powers and duties* NOW *vested* in them, shall be TRANSFERRED to and VESTED in the COMMISSIONERS, and shall be thenceforward exercised by them under the provisions of this Act," &c., &c.

Sir,—The Poor-law Board having the power, as evidenced above, "to regulate when they may see occasion the amount of salaries payable to officers respectively," the Committee of the Convention of Poor-law Surgeons take leave to memorialize you, who have already considered the position of Poor-law Medical Officers, that you may issue such orders as may secure a payment to them in accordance with the extent of their duties, and the cost incident to the supply of medicines and the maintenance of establishments needful for an efficient administration of medical relief to the sick poor.

Although your Memorialists have expressed the opinion, that a Board specially constituted for the supervision, control, and payment of Poor-law Medical Relief (now extended to near three millions of Her Majesty's subjects in England and Wales), with the whole cost thereof, derived from the Consolidated Fund, would be the best means to secure justice to the Union Surgeons, and the fullest advantage to the sick poor, they are willing to waive for the present this view of the subject, under a sense of the difficulties which beset its immediate introduction.

They beg, however, in the most earnest manner, respectfully to submit to you, that an exercise of the authority and power of the Poor-law Board, as shown to exist in the citations from the Acts of Parliament, would be equal to such a diminution of their admitted grievances, as might render their tenure of office, and the rigorous performance of their obligations, less painful and humiliating to themselves, and in many ways more beneficial to the suffering poor.

They, therefore, respectfully suggest—1st, That henceforth the Poor-law Board should, by a special order, direct that all appointments of Medical Officers be as durable as their good conduct and capability and willingness to continue therein.

2ndly. That the amount of payment be based on a calculation of the number of cases attended in a given district during the past three years; that the fixed salaries be arrived at by determining 6s. 6d. as the average sum to be paid per case throughout the country.

That the provisions of the Medical Order in 1842, for extras, be enforced in all Unions, and under all circumstances be made binding, except that the operations performed in the house be awarded the same fees allowed to out-door cases. Also, that a special provision be forthwith made to secure a just compensation for the enormous extra labours which are entailed upon the Union Surgeons through the Board of Health, under its general powers and regulations, more particularly during the presence of Cholera or other epidemics.

We beg to call your attention to the subjoined copy of a letter, recently received from the General Board of Health on this subject.

We have the honour to be, Sir,

Yours very respectfully,

THOMAS HODGKIN, Chairman.

CHARLES F. J. LORD, Hon. Sec.

July 23, 1849.

(Copy.)

Poor-law Board, Somerset House,
August 1, 1849.

Gentlemen,—I am directed by the Poor-law Board to acknowledge the receipt of the communication signed by you on behalf of "the Committee of the Convention of Poor-law Medical Officers," and to inform you, that the suggestions contained in the communication shall receive the best consideration of the Board.

The Committee are, however, so well acquainted with the subject of Poor-law medical relief, that it is unnecessary for this Board to point out to it the difficulties which exist to any immediate and general alteration or modification of the present system.

As regards the suggestion of the Committee, "that a special provision be forthwith made to secure a just compensation for the enormous extra labours which are entailed upon the Union Surgeons through the Board of Health under its general powers and regulations, more particularly during the presence of Cholera and other epidemics," I am directed to state, that the Poor-law Board are not empowered to lay down any prospective scale of remuneration for such services, but that the power of granting a reasonable compensation on account of extraordinary services is vested in Guardians, with the approval of this Board, by the proviso to Art. 172 of the General Consolidated Order, and that such power has already been acted upon in several instances.

I am, Gentlemen,

Your obedient servant,

W. G. LUMLEY, Assistant-Secretary.

To Thos. Hodgkin, Esq., Chairman, and Chas. F. J. Lord, Esq., Honorary Secretary of the Committee of Poor-law Medical Officers.

It should be observed, that no "prospective scale of remuneration" was sought from the Poor-law Board by the Committee. The memorial and application for relief arose less from the additional labours which an alarming epidemic like the cholera must induce, than from the vexatious returns and reports of cases for the public advantage, and the liability of the Union Surgeons under orders from the General Board of Health, to examine nuisances, and to report as officers of health.

The provision of Article 172 of the General Consolidated Order certainly might be sufficient to provide adequate remuneration to Medical Officers; but experience has proved, over and over again, that merely *permissive* clauses will not reach the existing evil, admitted by all concerned to be very great.

The answer from the General Board of Health in reply to the Committee appeared in your Number of July 21st; it throws the onus of providing for the Medical Officer upon the Poor-law Board; this Board politely hand the case over to the Board of Guardians. Mr. Mitchell's experience may be considered an average sample of the mode in which these functionaries will deal with applications for advanced payment to Medical Officers. Mr. Mitchell had been the Medical Officer to the parish for eighteen years. *Three halfpence* per cholera case, whether occurring night or day! He made equitable propositions to the Board, but the Lambeth Guardians paid no attention; in consequence he sent in his resignation, which was accepted.

Seeing the Union Surgeons thus bandied from one Board to another, and, as a body, redressed by none, the simple adage of "a fall between two stools" occurs to the mind; and even a saying of the quaint William Cobbett, about John Bull being persecuted by two sets of thieves,—the Whigs on one side, and the Tories on the other.

It is gratifying, however, to turn, for a moment, from this dark shadowing, to the light which breaks in from the Union to which Mr. Vallance, the intrepid advocate of a better system of Poor-law medical relief, is the well-tried Medical Officer. He reports, to the credit of the Board of Guardians of the West Ham Union, that a sense of justice has impelled them to pay 1*l.* per case of cholera, to whomsoever the professional attendant may be; and also 15 per cent. (for six months) upon the annual amount of the salaries paid to their Medical Officers, as some remuneration for their services as officers of health. If other Boards would obey the injunction of ancient Writ, "Go, and do thou likewise," there would be less cause to trouble you with these details.

I have the honour to be, Mr. Editor,

Your very obedient Servant,

CHARLES F. J. LORD, Hon. Sec.

4, Hanover-square, Aug. 12, 1849.

THE NATIONAL INSTITUTE.

The Third Annual General Meeting of this body was held at the Hanover-square Rooms, on Wednesday, the 8th inst.,

N. CLIFTON, Esq., in the chair.

The Chairman, in opening the proceedings of the evening, said: Gentlemen,—I cannot fail to express my regret, that the attendance of Members on the present occasion is so small; but I take it for granted, that this arises partly from the circumstance of gentlemen being so much occupied at this particular time, and partly because it may be thought that this is merely an official meeting, though really it is one of great importance to the Profession. The hopes and expectations which we had been led to cherish have been disappointed; but they were founded on the assurance, from official persons, that a Bill would be brought into Parliament for the better regulation of the Medical Profession. It had been the constant object of the National Institute to promote the objects of such a measure; and the Lord Advocate had stated to us, that it was his intention to lay on the table of the House such a Bill in the just closed session. That has not been done. Gentlemen are aware, that the position in which the Profession now stands has been brought about by the bad faith shown by the Council of the College of Surgeons, in respect to their late Charter, and the way in which they have carried out its provisions. Sir James Graham's Bill was only interrupted by this body, when we had almost been brought to realize our hopes. And during the last Session fresh conferences have been held, and the Delegates from the Council of the College of Surgeons had at first agreed to all that had taken place; but when they went back to the Council, this body repudiated what their delegates had before assented to, and left us in our present position. (Hear, hear.)

Mr. Ross, the Secretary, then read the Report.

This document consisted of a calm and lucid statement of the various important transactions in which the Council had been engaged during the past session of Parliament. During the session 1847-8, a Special Committee of the House of Commons was occupied in taking evidence upon the state of the laws governing the Medical Profession, and several members of a Conference representing the various interests that were to be considered and provided for by Medical Legislation, were called upon to give evidence. That Conference had already agreed to the principles of a general measure and to the outline of a Bill, which were submitted to the Committee. That Committee, however, broke up without making a Report, and the inquiry was thus suspended. On the re-assembling of Parliament, the Council were anxious that the Conference should resume its labours, and the necessity for taking further steps was pressed upon them, by the fact of the Legislature having, without consulting any formally constituted body, passed an Act by which four new Colleges were established in Ireland, with power of granting Degrees in Medicine, with more limited study, and at lower fees, than at present obtain. The Council of the Institute called the attention of Conference to this matter, and a meeting of the Committee of the latter body, was held, at which a Memorial was adopted to the Secretary of State, complaining of the difficulties likely to arise in the way of Medical Reform, and the adjustment of differences in consequence of this step,—tending as it would to lower the standard of Medical Education,—and entreating Sir George Grey to cause a *Bill*, founded on the labours of the Parliamentary Committee of the last two sessions, to be brought in speedily. After other meetings of the Conference, a Deputation from the Conference had an interview on the 5th of March with the Lord Advocate, when he gave assurance of the subject receiving his best attention and hoped to bring in a Bill. Up to this time, it had been supposed that the delegates of the Conference were agreed as to the leading principles of the proposed measure. On the 20th of March, however, the Council of the National Institute were informed, that a meeting of the Conference had been

called at the instance of the delegates of the College of Surgeons, for the purpose of ascertaining whether it was the intention of the Generall Practitioners that the application for a Charter was to proceed *pari passu* with a general measure or otherwise. The National Institute having replied in the affirmative, a resolution of the Conference to that effect was taken. On a second interview with the Lord Advocate, the Council of the Institute having asked his Lordship to report progress as to the promised measure, they were told that certain objections having been raised by the College of Surgeons, while he was still disposed to proceed with his Bill, he yet desired first to obtain the general accordance of the Conference Committee. Another meeting of the Conference was convened, and it then came out that the College of Surgeons objected to the New College having the power of examining in surgery, which the National Institute contended for, and as having been already established by resolutions of the Conference. Nothing, however, resulted from this meeting. At a subsequent interview of the Conference with the Lord Advocate, the College of Surgeons reiterated their objections, and the Delegates from the National Institute then read a Declaration to His Lordship, in which they represented that it was essential to a settlement of the Reform Question, that the General Practitioners should have the unrestricted right to regulate the education and examination of the Candidates for admission into their body, subject only to the general supervision of the controlling Council, and they believed that this right had formerly been conceded by all parties. This Document not leading to a reconcilement, the Lord Advocate stated that, in such circumstances, he could not think of advising the introduction of a Bill, recommending an arrangement of differences, and inviting another interview. At a meeting of the Conference, on May 2, a Resolution was unanimously agreed to, giving to the Council of the College of General Practitioners the power to direct the entire course of study, and to test the competency of Candidates for the Diploma of the College; but with an understanding that their competency to practice surgery should not be specified in the Diploma, such being provided for by the subsequent Examination of the Royal College of Surgeons. Since that period the Conference had not met, but a Deputation from the Institute had an interview with the Lord Advocate, at which His Lordship assured them that a Bill would be laid on the table of the House during the Session. This has not been done, and the explanation of Sir George Grey has already been given in our columns, (see *Medical Times*, August 4.) The Report then went on to explain the course pursued by the Council in relation to the views and proceedings of the Council of the College of Surgeons, and in conclusion reminded the members, that the object of a new Incorporation of the General Practitioners arose out of the conduct of the College of Surgeons in the administration of their last Charter, and the impossibility of opening the College of Surgeons to the General Practitioners, urging upon their members the necessity of strenuous exertions during the recess, to impress upon the Government the importance of the attention of Parliament being early called to the grievances of which the General Practitioners had so much reason to complain.

James Self, Esq., briefly moved the adoption of the Report.

J. Bowling, Esq., said: Having witnessed the exertions of the Delegates and the Council, I have great pleasure in seconding the motion; and when we take a retrospect we cannot but be grateful for the efforts which have been made,—efforts which but for extraneous causes, must, ere now, have led to a satisfactory result. But, Sir, I do not despair. I was one of the first to suggest an application to the College of Surgeons either to apply for an additional Charter, or that they should restore us to that position in the College to which we were entitled. In this, however, we have been disappointed; and, under these circumstances, we have no resource left us, but to place ourselves in opposition to the College of Surgeons. No one but must feel that we have been degraded from our rank into the position of Licentiates, and thus to hold the candle to young men who are elected into that College by favouritism. Forty years ago I passed that College, paying a large fee at the time, and a subscription of a guinea a year; and yet now I am put below men who had been apprenticed to persons of my own standing. But one thing is more mortifying to me than all besides, namely, that those are allowed to supersede us, many of whom have committed some of the grossest blunders ever committed in surgery. We have no wish to encroach. It has been said that the College contains the best Museum and the best Library in the world; and yet, what has the Council done? They have disgusted every one in the Profession, except their own *protegès*, some of whom have been compelled to go out of the country for misdeeds in their Profession. Now, the object of the Charter was to secure a constituency for election to the Council; but how could men in Jersey, or elsewhere, form a constituency? And so the kindness of Her Majesty in granting the Charter has been countervailed. It is lamentable when we see the influence exerted on Her Majesty's Government by the Council of the College of Surgeons, and hardly to be borne that these men should have such power as to prevent the proceedings which Ministers intended; and yet it is quite plain that they have done this over and over again. It is notorious, putting the claims of the Profession quite out of the question, that the welfare of Her Majesty's subjects requires that something should be done for the regulation of the Profession. To show what is the exact position of the people in this matter, in the last examination at the College a member was compelled to undergo a second examination before he could be allowed to practise in the Navy. Now, if the examination for membership is so bad, that a Licentiate cannot attend a sailor, I should like to know how he is competent to attend any of Her Majesty's subjects. (Hear, hear.) Our only plan is "Agitate! Agitate! Agitate!"—if we do this, I think we shall, at any rate, get some redress, and that we shall thus contribute to the welfare of the Profession and the public at large.

The motion was then put and carried.

The second resolution was moved by Thomas Martin, Esq., of Reigate, and seconded by — Self, Esq., and was as follows:—

"That this meeting declare their surprise and disappointment, that, after all the discussions and negotiations which have taken place, and the ample evidence that has been afforded, the Government should not, upon its own responsibility, have brought in a Bill, during the recent session of Parliament for the efficient education and regulation of practice of the Medical Profession."

Carried unanimously.

J. Propert, Esq., moved—

"That the delay of Medical legislation has been productive of the most grievous evils, both to the public and the Profession, inasmuch as a large body of imperfectly-educated Practitioners have commenced practice, presuming upon the amnesty which any future legislative measure would necessarily afford them."

This resolution was seconded by James Clayton, Esq. Mr. Self, in support of the resolution, stated, that in a record which he had kept of the Medical Profession in his district, he had found that there were 330 medical men, of whom 72 were unqualified, and of the latter number one-half were without a tittle of qualification, and within the last twelve month he had to add ten more to this list; thus showing the necessity of better regulation for the Profession.

This motion having been carried,

Robert Tanner, Esq., moved, and George Robins, Esq., seconded:—

"That this meeting cordially approve of the principle enunciated in the letter of the Council of the Institute to Mr. Guthrie, in which they reiterate the original object of the National Association, to seek for a new incorporation of the General Practitioners, in default of obtaining for the members full admission to the privileges of the College of Surgeons."

Carried.

The fifth resolution was moved by Richard Wallace, Esq., and was as follows:—

"That this meeting cannot too strongly urge upon their medical brethren the necessity of united action; and they recommend that the Council of the Institute do forthwith convene a general Conference of Delegates from the various Associations that have been established for the purpose of effecting a reform of the laws governing the Medical Institutions of the Kingdom, for the special purpose of securing as extensive a union of sentiment and action as possible upon the main principles of Medical legislation;"

which having been seconded by — Nicholson, Esq., Dr. Burnett rose to support it, and said: The origin of this Institute was from the annoyance felt among members of the Profession at not being allowed to take a part in the legislation of their own College. But I always held that this was only a partial view of the question after all; because the great object is, that the whole Profession should be put on a proper foundation. We are the creatures—the abortions of the College, and they have made any use of us they pleased. I consider that if we have any claim to take rank as a nation, it is that we hold the high attributes,—justice, truth, and mercy; and when we allow men—any men—to have an influence over our Ministers, we, as a people, are in a state not to be envied; we may, indeed, have a free-trade in corn; but Ministers must beware, or by-and-bye, we shall also have a free-trade in Ministers. I propose that we should do nothing precipitately; I am determined to carry out the purpose for which I joined this Institute, and it matters little to me to how few or to how many I speak; but we have everything in our power, simply because we have on our side truth and justice. (Hear, hear.) I have felt much sympathy with those who have met together to endeavour to remedy the grievance of the Union Surgeons, but cannot help feeling that they are not attacking the disease at its root so long as this great evil remains untouched. I therefore propose that we take the opinion of the bodies specified in the Resolution, and after that, if we fail in gaining our object, then several methods are open to us. As freemen of this country, we can go before the Queen. It may be said, "This is all very well, but after all, she must refer the matter back to her Ministers." But that Minister will be a bold man who will advise the Queen to refuse us justice. Instead of being depressed, we have considerable reason to feel that the power is in our own hands to obtain what we want, knowing that, in the end, we shall conquer; and, therefore, I hope ever to stand by the cause of justice to the Profession.

This resolution having passed unanimously, G. J. Squibb, Esq., moved, and H. P. Fuller, Esq., seconded,—

"That the election of officers and Council be suspended during the ensuing year."

Before putting the resolution,

The Chairman said: I think this proposal will commend itself to every well-wisher of the Institute. If the bye-law were carried out, we should lose one-third of our original Councillors, and that number would consist of the most active gentlemen among us.—Motion put and carried.

At the conclusion of the business, the Chairman said: I believe the fifth resolution is fraught with much of good to the interests of the Profession. Many of these gentlemen are at variance with us, but I think it is for want of discussion. It remains for us to reconcile discrepancies amongst Medical Reformers, and to meet in conference those bodies who have various ideas on the subject. The question for the Profession is, Will you come and lay claim to all the privileges of the College of Surgeons? and if they will not do this, then the only alternative is an independent Corporation; either they must consent to be degraded as Members of the College of Surgeons, or must seek to make that for themselves which is now denied them. So that the discussion lies in such a small compass, that if we can only get the Profession to meet, it must end in unanimity. We have great reason to complain of the insults offered to the old Members of the College of Surgeons; they (the Council) improperly place themselves above their Members, and create another body over their heads, and hence we, by that proceeding, have been degraded. Surely gentlemen will not sit down quietly under such treatment. (Hear, hear.)

A vote of thanks to the Chairman was then passed, to which that gentleman responded, and the meeting separated.

THE ALLEGED BRIDGNORTH MATRICIDE.

The trial of Mercy Newton, on a charge of murdering, and subsequently attempting to burn the body of her mother, is, perhaps, the most extraordinary case of its kind in the annals of English judicature. The indictment itself, in the abstract, and in the revolting nature of its details, must ever stand prominently amongst the criminal horrors of this country. Analogous cases are, happily, not common amongst us, and it is, therefore, that the breadth and brutality of the allegations, in the instance referred to, give it a fearful conspicuousness in the great calendar of crime. But, in another respect, is this case one of the most anomalous interest; viz., in the seeming inability of the prosecution to obtain a conviction, or the defence an acquittal, of the prisoner. Nine several Coroner's juries were holden at Bridgnorth, on the very spot of the assumed tragedy, with every facility of investigating the minute circumstances of the occurrence, and of determining whether it were the result of accident or of design, and yet not one of these juries could agree! Whether it were that the several members thereof were so blind that they could not distinguish between right and wrong, or so bigotted that they would not admit the difference, it is not our province to determine. The fact of the inconclusiveness is on record; and whether it indicate a want of honesty, or a want of head, on the part of the Bridgnorth jurors, will, perhaps, remain a *quæstio vexata* to the end of the chapter; but it would certainly seem to say very little for the intelligence, or the integrity, of nine times twelve "honest men," that the opportunity of comparing evidence and counter-evidence, did not enable them to say *aye* or *no!* But so it was; and the unhappy woman, after as many escapes for her life as are usually allotted to the feline tribe, was committed by a magistrate's warrant on a charge of murder, which a succession of coroner's juries did not believe to be valid. Parties differing thus widely can, of a verity, not both be right. It would be an interesting metaphysico-legal curiosity to hear the conflicting logicians contending for an inference, by comparing notes with one another. We cannot help thinking that the epithet *ne sutor ultra crepida* would apply equally to either of them.

To have done, however, with Bridgnorth, we must direct the reader's attention to the Shrewsbury Assizes of last March. On the 21st of that month, the prisoner was put upon her trial before Mr. Justice Coltman and an intelligent jury, charged with having murdered her mother in one of nine different ways, the absence of demonstrative proof of her guilt having rendered it expedient to frame the indictment with these several counts. The case was detailed by the prosecuting counsel, Mr. W. Whitmore, with much minuteness and circumstantial precision; numerous witnesses were called, examined, and cross-examined at great length; there was an eloquent and ingenious address from Mr. Huddlestone for the defence; a lucid and deliberate summing up by the learned judge; and the jury, unable at once to come to a verdict, were locked up, so that they might draw their inference at leisure.

Not only in a legal, but in a medical sense, is this trial of significant consequence, and calculated to figure prominently in the forensic literature of this country. It is in this acceptation that we introduce the subject to our readers. The main weight of the trial rests upon two questions, viz.: What was the cause of death? and were the burns found upon the body produced before or after death? The professional evidence might be divided into two kinds—that which was given by the parties who had made an examination of the body itself, and who reported its special appearances; and that which was adduced by other parties who were called upon to give a scientific opinion based upon the reports of the inspectors. The former were Mr. Coley, Mr. Newall, and Mr. Thursfield, of Bridgnorth; the latter, Dr. Wright and Mr. Bolton, respectively Professors of Clinical Medicine and Practical Anatomy in Queen's College, Birmingham. We shall give the substance of their evidence on the two occasions connectedly; this will be a saving of space to our columns, and a preventive of confusion to our readers.

The Bridgnorth medical witnesses were of one opinion as to the appearance of the brain, lungs, and heart, viz., that the two former were excessively congested throughout their substance with black fluid blood, and that the right cavities of the heart were completely engorged with a similar material. The body was burnt from the knees upwards, and chiefly in front. In some places it was black; in others, brown and coriaceous-looking; and in others, merely shrivelled. In no place throughout the body was there a mark or line of redness. There was what appeared to be a vesication at the lower part of one leg, from which about a teaspoonful of fluid was liberated by Mr. Coley, who, however, employed no means to discover the nature of it; thought it might be serum, though there was no redness around the vesication, or any underneath the detached skin. The stomach contained only a little bread and cheese, and beer; there was no poison in it. The lips were burnt; the tongue slightly protruded beyond the teeth; its tip was scorched, and the other part of it was livid from congestion. On the third day after the burning, the tongue was so swollen, that it nearly filled the mouth. In addition to these details in chief, and some minor ones, the witnesses severally gave it as their opinion that the deceased had died from suffocation, and that the burns found upon her were produced after death.

Dr. Wright was next called, and examined by Mr. Whitmore. He stated: I am a Physician practising at Birmingham; am Professor of Clinical Medicine in Queen's College, and Physician to Queen's Hospital, in that town. Have seen many cases of burns, and examined many bodies that have died from burning. Have studied the subject in connexion with pathology. Have studied the subject of asphyxia, and written a prize treatise thereon. Have heard the Medical evidence given this day. Am of opinion therefrom, that the deceased died of suffocation. Entertain this belief from the congested state of the brain and lungs (particularly the latter), the absence of signs of inflammation, and especially from the engorgement of the right side of the heart. There are various ways of producing asphyxia, (which, in effect, is simply the exclusion of atmospheric air from the lungs. Do not believe that an individual could breathe flame. Its admission within the mouth would cause instant spasm of the glottis. Do not believe that where there was consciousness,* and power of movement, an individual could be suffocated by flame, unless completely surrounded by it. The same access of oxygen that will support combustion will support respiration. Carbonic acid,* and carburetted hydrogen, are poisonous gases; they do not destroy life by producing asphyxia, nor do they cause the same amount of congestion as is observed in suffocation. Bleeding from the ear is not an uncommon occurrence in death from asphyxia; it generally happens in hanging, and sometimes in drowning. Have known it occasioned by the falling of a heavy body upon the head. Have never known a human body burnt after death. Believe it could not occur except by accident, or by design for criminal or experimental purposes. Believe in the possibility of a vesicle containing serum being produced by the application of flame to the body within five minutes after death.

* Cross-examined by Mr. Huddlestone: Have never known a blister produced upon a recently dead body. Form my opinion from physiological reasoning. Am inclined to believe that the vesicle said to have been found upon the leg of the deceased, was a *post-mortem* production, because of no appearance of vital burn being near it, no redness around it, and none underneath the separated cuticle. Think, decidedly, that the *post-mortem* appearances indicated death by suffocation. Sudden death from fright or pain would not furnish such appearances. Spasm of the glottis may be a cause of suffocation. In death thus produced, additionally to other appearances, there would probably be frothy mucous in the trachea and bronchi, perhaps congestion of the blood-vessels, and perhaps extravasation.* Have never known vital burning, in a comparatively healthy subject, without a line of redness demarcating between the injured and the uninjured parts. A broader blush of inflammation comes on subsequently, and disappears before the former. Am not able to affirm, from my experience, that a vital burn can occur in a healthy individual without the red line of demarcation. Cannot, on such a subject, reply affirmatively to a negative proposition.

Mr. Bolton was called and examined by Mr. Philimore: Am a practising surgeon at Birmingham, and lecturer on Practical Anatomy in the Queen's College there. Have studied the subject of vital burning, and have seen many cases of it. Have heard the medical evidence to-day, and concur with it, that the deceased died from suffocation. I think no person could die from burning, except under peculiar circumstances, without screaming. It is highly probable, that a flame increasing in intensity would cause a person to scream. Spasm of the glottis would prevent respiration of flame. The swelling of the tongue was no doubt due to congestion of the organ. That congested state would favour decomposition and swelling: if the tongue had been black from charring, decomposition would have been retarded. A person could not be suffocated by flame, unless surrounded by it, or, unless there were some mechanical obstacle to escaping from it. Was of opinion, from the absence of all marks of redness, that the burns were caused after death.

Cross-examined by Mr. Huddlestone: The absence of oxygen would cause suffocation. Believed the burning to have occurred after death. There might be a vital burn without a blister, as when the part was completely charred. Then, the blister, if any had been, was destroyed. Had seen such cases in colliery explosions; but they did not resemble the present one, inasmuch as the bodies were burnt all over. The flattening of the nose might be before or after burning. It would be difficult to flatten a prominent nose by pressure; burning would shrivel it, and it would then become brittle. Had seen a body charred all over, (by colliery explosion,) except a few spots, and in those there were marks of redness.

ALLEGED POISONING BY LOBELIA INFLATA.

CASE OF THOMAS WILSON.

Reported by Dr. PEARSON and Mr. CURTIS.

Was called to attend this lad at a quarter past seven, a.m., of the 16th of April last; found him complaining of pain in the belly, and pain in voiding urine. The history received from the friends was, that he had suffered occasionally, for a considerable time, from constipation, and had frequently complained of what the father described as a coldness of the belly; that for the relief of these he had frequently taken mountain flax, yarrow, and Cayenne pepper. When first seen, his pulse was quick, small, and easily compressed; tongue covered with a white fur; belly tympanitic, but not painful when percussed. Having to go into the country, he was not seen again until half past three, p.m., when, immediately on entering the room, it was evident a rapid change had taken place; his countenance was pale, ghastly, and anxious in the extreme, and bore the appearance of the system having sustained a great shock, such as might result from an accident with severe internal lesion; skin mottled; no pulse at the wrist; the action of the heart very feeble, and its sounds scarcely to be distinguished from each other; breathing extremely laboured, belly still tympanitic; the senses appeared to be dull, but he answered questions. The matters vomited before our visit had an olive colour, and were not unlike the coagulated blood deposited from beef tea; the stools were scanty, and contained membranous shreds in large quantity.

It being now evident that there must be more than ordinary disease to account for the rapidity and character of the symptoms, after examining the parents of the lad for a considerable time, and naming various vegetable, depressing poisons, likely to produce such results, we learned that lobelia inflata had been administered. We prescribed, but the patient died before medicine could be administered.

Post-mortem examination made about forty hours after death:—

General conformation good; of slender make but muscular; belly green from putrefaction—enormously distended; mottled appearance of various parts of the skin, evidently depending upon gravitation of fluids.

The peritoneal surface of the intestines completely covered with lymph in large quantity; the intestines adherent everywhere, but separable by the finger, and presenting a vascular pinkish and slightly granular appearance; the liver of a blackish colour; the gall-bladder moderately filled with inspissated black bile, containing numerous minute needle-shaped crystals.

The internal surface of the stomach greatly inflamed,—inflammation especially recent at the cardiac orifice, also marked and recent at the pyloric orifice.

The great and small intestines more or less inflamed throughout, but very recently in the duodenum and upper part of the jejunum, in which was found a large incipient chronic ulcer. The papillæ of the tongue enlarged; the pharynx and œsophagus congested; several lumbrici found in the intestines and œsophagus; the fæces appeared of ordinary quantity, they were but slightly coloured with bile. The liver slightly congested and sooty in colour, otherwise healthy; the pancreas congested; the lymphatic glands congested; both kidneys congested and watery. The bladder empty; capillary injection at the neck.

On opening the chest, the contents have a nearly healthy appearance; the lungs, however, having a slight pink colour; extensive adhesions are found be-

tween the opposing surfaces of the pleuræ of both sides, evidently the result of old disease, and are mostly situated at the lower lobes, which are much gorged with blood, and contain an accumulation probably of mucus; the pleural surface of the diaphragm congested; the pleuræ conjointly contain about twenty ounces of serum.

The entire surface of the mucous membrane of the larynx and trachea show signs of inflammation old and recent, and extending throughout the bronchi; fibrinous clots are found loose in the larynx. In the course of the anterior raphé of the heart is seen an enormously distended lymphatic vessel; the right vetricle contains a polypus; otherwise healthy. The brain and its membranes greatly congested; no fluid in the ventricles.

REMARKS.

It is our firm conviction, from this case, and from the careful experiments we have made with the drug upon animals, that not only the recent inflammations and congestions had been caused by it; but that the signs of chronic inflammation in the alimentary canal, peritoneum, bronchial tubes, &c., had also been caused by this or some other irritant given at intervals for a considerable period, as recommended by these people.

The Counsel for the defence did not question the poisonous nature of lobelia, but endeavoured to account for the *post-mortem* appearances from natural causes; and in order to do so he took *permanent obstruction* of the bowels, (which never existed,) as his foundation, although I told him it was not present in this case. He framed his questions in such a manner as to lead the Judge and jury to believe, that they referred to Wilson's case;—thus, *might* not *obstruction* cause inflammation of the bowels? *Might* not not this spread to the stomach? *Might* not this spread to the peritoneum and bladder? *Might* not these cause congestion of the lungs and brain? What medical man could undertake to say what such a mass of disease *might not* do. It *might* more reasonably be doubted whether such a mass of *acute* inflammation ever existed in the same subject at the same time; at all events, it could not arise in this case from a state of things which never had any existence. Again, he examined on the poisonous action of opium, though the patient never took any of that drug from us.

UNIVERSITY OF LONDON.

M.B. FIRST EXAMINATION.—PASS EXAMINATION.—1849.

ANATOMY AND PHYSIOLOGY.

Monday, August 6.—Morning, 10, to 1.

Examiners, MR. KIERNAN and Prof. SHARPEY.

1. The frontal and parietal bones being removed, describe the surface comprised between the remaining portion of the margin of the orbit anteriorly, the superior margin of the petrous portion of the temporal bone posteriorly, and the median plane internally; commence the description at the margin of the orbit, and proceed towards the posterior limit, mentioning the portions of bone entering into the formation of the part to be described, the sutures, fissures, and foramina (and the parts occupying them in the fresh state,) in the order in which they occur.

2. Commencing at the integuments on the posterior aspect of the thigh, describe the parts which would be met with in fully exposing the posterior surface of the Abductor Magnus muscle.

3. Commencing the dissection at the integuments, describe the parts brought into view in exposing the Omo-Hyoideus from the point at which it emerges from behind the clavicle to its insertion.

4. Give a brief account of the system of the Vena Portæ, mentioning its condition in the fœtus, the changes which take place after birth, and any points in which it resembles, or differs from, the general venous system:—and, the walls of the abdomen being removed, describe the steps of the dissection required to expose the course of the Splenic Vein, the terminations of the Inferior and Superior Mesenteric Veins, and the trunk of the Portal Vein as far as its entrance into the Liver; mentioning the relations of these veins to other parts.

5. Describe in their relative position the parts brought into view on removing the undermentioned muscles, viz.:—

The Pectoralis Major and Deltoid.
The Glutæus Maximus.
The Trapezius.
The Gastrocnemius, Plantaris and Soleus.

ANATOMY AND PHYSIOLOGY.

Monday, August 6.—Afternoon, 3 to 6.

Examiners, Mr. KIERNAN and Prof. SHARPEY.

1. Describe the hip-joint, giving an account of the acetabulum and of the upper extremity of the femur, of the cartilages, synovial membrane, and ligaments, and of the movements which take place in the joint, mentioning the muscles by which they are severally affected. Compare the shoulder and hip-joints as regards their contruction and movements.

2. Commencing at the skin of the Perineum, give the dissection required to expose as much of the Levator Ani as can be seen in this situation, describing the parts in the order in which they occur.

3. Give the dissection required to display the Flexor and Pronator muscles on the fore-arm; describing, in the order in which they would be exposed, the muscles, fasciæ, ligaments, vessels, and nerves met with in the dissection, which is to be limited below by the wrist.

4. Describe the situation, connexions, form, and structure of the Uterus, Vagina, Fallopian Tubes, and Ovaries, with their vessels and nerves.

5. Give an account of the structure and arrangement of the Choroid Coat and Iris; mentioning briefly the uses assigned to these parts of the organ of vision.

6. Give an account of the structure and chemical composition of Articular Cartilage.

CHEMISTRY.

Tuesday, August 7.—Morning, 10 to 1.

Examiner, Professor BRANDE.

1. *Oxygen*, *hydrogen*, and *nitrogen*, are required *perfectly pure*: describe the modes of so obtaining them, and of testing their purity.

2. State the distinctive chemical characters of *potassa*, *soda*, and *lithia*—and of *baryta* and *strontia*; and how the three former, and the two latter, may be analytically separated.

3. Define the terms *Isomorphism* and *Isomerism* as applied in Chemistry, and give several illustrative instances.

4. What are the usual constituents of the common *fixed oils*, and how are those constituents separated and purified? Give their formulæ.

5. Describe the best modes of preparing *emetic-tartar*, the *oxysulphuret of antimony*, and the *antimonial powder* of the Pharmacopœia, giving their atomic composition, and that of the several *oxides of antimony*.

6. How may *Quinia* be best obtained? what is its composition, and what are its distinctive characters, as opposed to those of *Cinchonia*? State the composition of *Sulphate of Quinia*, and the tests to which you would submit that salt with a view of determining its purity.

MATERIA MEDICA AND PHARMACY.

Tuesday, August 7.—Afternoon, 3 to 6.

Examiner, Dr. PEREIRA.

1. Enumerate the officinal substances commonly termed Narcotics, classifying them in natural-history order. State first their general physiological effects, then their individual peculiarities of operation. Mention their respective therapeutical applications, and the cautions to be adopted in the employment of each. Lastly, give a sketch of the treatment of narcotic poisoning.

2. Give a sketch of the pharmacological history of Arsenious Acid, to include

α. Its manufacture.
β. Its composition and properties (physical and chemical).
γ. Its tests.
δ. Its effects both in medicinal and in poisonous doses.
ε. Its therapeutical uses, the cautions to be observed in its employment, and its dose.
ζ. The mode of preparing, the strength, and the dose of *Liquor Potassæ Arsenitis*, Ph. Lond.
η. The treatment of arsenical poisoning.

3. Give a brief botanical description of *Papaver somniferum*. Describe the method of obtaining Opium; give a sketch of the process for the extraction of Morphia; and describe the physical and chemical properties of this alkaloid.

4. What is the cause of the black line on the gums in poisoning by lead; of the black colour of the stools after the use of chalybeates; and of the slate colour of the skin after the prolonged employment of nitrate of silver?

5. How would you distinguish a pure solution of bicarbonate of magnesia from an extemporaneous solution of sulphate of magnesia and bicarbonate of soda?

BOTANY.

Wednesday, August 8.—Morning 10 to 12.

Examiner, Rev. Professor HENSLOW.

"Questions restricted to the limitations specified by Syllabus for Pass Examination."

1. Define the terms Inferior, Loculicidus, Corolla, Folliculus, Placenta, Spatha.

2. Give such diagnoses of the following Orders as may be sufficient to include our British genera:
Lineæ, Compositæ, Labiatæ, Aroideæ.

3. Give such diagnoses of the following Genera as will include our British species—alluding also to such of the more important or prominent peculiarities in the flower, fruit, and seed, as you may happen to remember:
Helleborus, Apium, Convolvulus, Salix, Carex.

M.B. FIRST EXAMINATION.

FIRST DIVISION.

Lionel Smith Beale, King's College; Thomas James Duthoit, St. Bartholomew's Hospital; Edward Abraham Hancock Head, King's College; Joseph Houlton, Charing-cross Hospital; Robert Coane Roberts Jordan, King's College; John Phillipson Lpngham, University College; George May, King's College; Richard Neale, University College; Wm. Odling, Guy's Hospital; Charles Pardey, King's College; John Sherwood Stocker, Guy's Hospital; Henry Thompson, University College.

SECOND DIVISION.

Nathaniel Philip Betts, University College; Jas. Charles Dickinson, King's College; James Newton Heale, St. Thomas's Hospital, Richard Hunt, Guy's Hospital; James Jones, Royal College of Surgeons of Ireland; John White Keyworth, St. Thomas's Hospital; Harry William Lobb, St. Bartholomew's Hospital; David Henry Monckton, King's College; John Barclay Scriven, University College; John Patrick Smith, Jervis-street Hospital, Dublin; William Palmer Steele, King's College; James Vaux, King's College; George Webster, University College.

SOUTH LONDON MEDICAL SOCIETY.

A Meeting of this Society was held on Thursday night, called by public advertisement and circular, at the Literary and Scientific Institution, Borough-road, for the special discussion of the nature and treatment of cholera. J. Hilton, Esq., in the chair.

Peculiar interest appeared to have been awakened by the announcement, resulting, as it did, in an overflowing meeting of gentlemen; but so far either as the diagnosis, the nature, or the treatment of cholera was concerned, we cannot say that much benefit is likely to arise from it, excepting in so far as the discussion may incite to more diligent inquiry. Nearly three hours were occupied in a most animated discussion, and still *there is no specific for cholera*. The methods of treatment stated as having been adopted,—whether opium, calomel, the saline or saline injections, and many others,—all these had been partially beneficial, but in the majority of instances without success; indeed, one speaker gave it as his experience, that "no treatment" was the best. Then the *vexata questio* came up, as to the contagiousness or non-contagiousness of this mysterious disease, and "the House" was pretty equally divided, but somewhat agreed as to locality favouring other predisposing causes; though even this idea was attacked. To sum up in few words, we must still record, that the Cholera continues to baffle science and the curative art, and lays a fearful responsibility on those who are constituted for the especial purpose of guarding the public against noxious influences. One thing, at least, was certain, that, in multitudes of instances, to neglect of diarrhœa and premonitory symptoms, and sanitary precautions, was to be attributed the fatality of the disease. The speakers were, besides the Chairman, Messrs. James Hicks, P. J. Murphy, the Hon. Secretary, — Wright, Waterworth, Hunter Lane, Hawkins, Dr. Murphy, Dr. Barlow, Dr. G. O. Rees, Mr. B. Evans, Dr. Crisp, Mr. Dendy, and Mr. Taylor. At the conclusion of the discussion an adjournment was moved, seconded, and carried, to the 30th of August, in the hope that by that time, either larger experience might lead to something more satisfac-

tory, or that an abatement of the disease might allow time to those of the Profession who have been so deeply engaged, to study more deeply the characteristics of the disease and the treatment to which it might be said most to succumb.

MEDICAL NEWS.

APOTHECARIES' HALL.—Names of gentlemen who passed their examination in the science and practice of medicine, and received Certificates to practise, on Thursday, August 9, 1849:—John Langford, St. Leonard's-on-Sea; William Martin Hatfield, Chilham, Kent; Louis Parnell; John Newton Coffin, Devonport; James Rhodes, Manchester.

ROYAL COLLEGE OF SURGEONS.—The following gentlemen, having undergone the necessary examinations for the diploma, were admitted members of the College at the meeting of the Court of Examiners, on the 10th inst.—Messrs. Charles Henry Payne, Uphill, near Bristol; Archibald Prentice Childs, Bungay, Suffolk; John Parker, Chester; Robert Jones, Conway, Carnarvonshire; William Henry Peacey, Tewkesbury, Gloucestershire; Frederick William Armstrong Rawlins, Congleton, Cheshire; Samuel John Tracey, St. Bartholomew's Hospital; Richard Symes, Bridgewater; James Tilby, United States; Samuel Reeves, Plymouth; William Holman, Plymouth; Walter Monday, Olveston, Gloucestershire; and Bernard Chapman Dolman, Melbourne, Dorsetshire. Admitted on the 13th inst.:—Messrs. Richard Close, Dublin; Edward John Daniel, Archway-road, Highgate; Edward Snell, Clare, Suffolk; Robert Harrison Wilson, Howdon Pans, near Manchester; George Elin, Regent's Park Thomas Wynne Williams, Denbigh, North Wales; Augustine Ernest Fitzgerald, Dublin; and Benjamin Alfred Robinson, London. At the same meeting of the Court, Mr. Charles Paget Mingaye passed his examination as a naval surgeon. This gentleman had previously been admitted a member of the College, his diploma bearing date May 30, 1845. The following gentlemen were admitted members on the 15th inst.:—Messrs. Cecil Crandell, Royal Navy; Basil Egaton, Birmingham; William Weaver Jones, Cleobury Mortimer, Salop; George Smith, Stroud, Gloucestershire; Thomas Collyns Blanchard, Southampton; Edward Rutley Ray, Milton, near Sittingbourne; Thomas Peregrine James, Abergavenny, Monmouthshire; Thos. Wallscourt Blake Greaves, Tuam, Galway; James Breach, Bradfield, Berkshire; Henry Benjamin Lillie, Colchester; Richard Lee, Thames, Oxfordshire; and William Strong Browne, Camberwell.

THE COLLEGE FELLOWSHIP.—The following gentlemen, all members of the College, with one exception, having undergone the necessary examinations, were admitted "Fellows" of the Royal College of Surgeons, at the meeting of the Council on the 16th inst.:—Messrs. Samuel Allen Bindley, Birmingham, diploma from the College dated ——; Peter Ladwick Burchell, Kingsland-road, July 5, 1839; Edward Dennis Hacon, Hackney, July 3, 1840; Edward Law Hussey, Oxford, February 7, 1845; Henry Thomas Leigh, Turnham-green, Middlesex, February 13, 1829; Thomas Littleton, Saltash, Cornwall, May 7, 1847; John Morgan, Albion-place, Hyde-park-square, April 30, 1841; Edward Palmer, Westminster; George Hill Smith, Stevenage, Hertfordshire, November 17, 1837; and Frederick Wildboor, Ealing, Middlesex, formerly House Surgeon of the Westminster Hospital, April 7, 1843.

APPOINTMENT to the Chair of Materia Medica, Queen's College, Cork, Dr. Alexander Fleming, of Minto-street, Edinburgh.

DENTIST TO PRINCE ALBERT.—In justice to Mr. Saunders, who, we have the means of knowing, is the only Dentist employed by His Royal Highness, we think it right to re-state in this place what was officially announced in an Advertisement by Lord Abercorn in our Journal of last week, that the appointment given by inadvertence to Mr. Robinson, of Gower-street, has been cancelled.

CAMBRIDGE-HOUSE, Aug. 4.—The Duke of Cambridge has been pleased to appoint Edward Henry Sieve King, Esq., M.D., Member of the Royal College of Physicians, to be one of His Royal Highness's Physicians.

WAR OFFICE, Aug 4.—67th Foot—Acting Assist.-Surg. John Duff to be Assist.-Surg., vice Blatherwick appointed to the staff. Hospital Staff—Staff Assist.-Surg. Thomas Rose Dyce to be Staff-Surg. of the Second Class, vice Home promoted Assist.-Surg. Thomas Blatherwick, from the 67th Foot, to be Staff-Assist.-Surg., vice Dyce, promoted. Memorandum—The following appointments, inserted in the *Gazette* of the 13th of July, 1849, have been cancelled:—Hospital Staff—Assist. Surg. Henry Franklin, from the Third Light Dragoons, to be Staff-Surg. of the Second Class, vice Home promoted; 3rd Light Dragoons—Assist. Surg. Vere Webb, from the 10th Foot, to be Assist. Surg., vice Franklin promoted on the Staff; 10th Foot—Staff-Assist.-Surg. James Lewis Holloway to be Assist.-Surg., vice Webb appointed to the 3rd Light Dragoons. Hospital Staff—Acting-Assist. Surg. John Duff, M.D., to be Staff Assist. Surg. vice Holloway appointed to the 10th Foot. The Christian names of Ensign Furnell, of the 3rd West India Regiment, are "Paul Cudmore."

OFFICE OF ORDNANCE, July 31.—Ordnance Medical Department—Surgeon William Richardson, M.D., to be Senior Surgeon, vice Fogo retired; Assist.-Surg. William Alston Dassauville, M.D., to be Surgeon, vice Richardson.

THE COLLEGE LIBRARY.—It may save many of our readers some trouble by our informing them that the Library of the Royal College of Surgeons will be closed on the 24th inst., and re-open on the 25th of September, after which the hours of admission will be from 12 till 6, instead of 10 till 4, as heretofore. This alteration has been conceded by the Council to some gentlemen signing a memorial to keep the library open till a later hour.

OBITUARY.—On the 9th ult., at Madeira, in the 34th year of his age, Dr. Gilham, most deservedly lamented and respected. His skill elevated him to a high position in his profession, to which he was an ornament. Madeira has sustained a loss that will be long felt; in fact, it is looked on as a general calamity. His remains were attended by a numerous company of Portuguese, English, and a great number of poor: to the latter he was very kind in giving his professional advice.—At Edinburgh, 23rd ult., Dr. William Robertson, late Surgeon 12th Regiment of Foot.—At Paisley, 2nd inst., John Finlay, M.D., of Glasgow.—On the 30th ult., at his residence, in Bedford-square, John Scott, Esq., M.D., aged 66.—On the 4th inst., at his residence, in Wimpole-street, Sir Charles Scudamore, in the 70th year of his age.—On the 10th inst., at his house, No. 41, Jermyn-street, after a few hours' illness, Henry Burton, M.D., Senior Physician of St. Thomas's Hospital.—On the 9th inst., after a short illness, Mr. William Munro, formerly of Dingwall, N.B., and for several years the faithful assistant of Mr. Angus Kennedy, Surgeon, Stratford, Essex.—On Saturday, the 11th inst., at Henley-on-Thames, aged 77, John Henry Judson, Esq., 47 years a Medical Practitioner at Ware, Herts.—At Hong-Kong, 11th April, on board of H.M.S. Alligator, William Henderson, Assistant-Surgeon, Royal Navy, eldest son of William Henderson, Esq., Rosehall, Newington.

THE CHOLERA.—The reports from the provinces during the past week in reference to the cholera have, upon the whole, been favourable. In many towns the disease is on the decline, while in some few it is either stationary, or has exhibited a tendency to increase. This has been the case at Bristol and Salisbury; the deaths, however, have not been so large in proportion to the attacks as in the week preceding. Cholera is spreading through some of the provincial towns in France. It has also appeared in Spain, where the heat has been very intense. The deaths in London during the week ending Saturday, August 11, were 1909. The mortality is somewhat less than it was in the previous week. The deaths from all causes in the last six weeks were 1070, 1369, 1741, 1931, 1967, and 909; of which 393, 680, 1002, 1173, 1308, and 1185, were by diseases of the zymotic class. Small-pox, scarlatina, and hooping-cough are comparatively quiescent; typhus is more fatal than it was. The excess of 901 deaths over the average is due to diarrhœa and cholera, which were fatal to 173 and 823 persons. The deaths from cholera during the last six weeks were 152, 339, 678, 783, 926, and 823. The decrease is gratifying; but it is right to observe that the improvement is chiefly confined to West London, Poplar, St. George (Southwark), Newington, Camberwell, and Lambeth. The deaths from cholera in the two last weeks were 29 and 48 in Wandsworth; 9 and 21 in Pancras; 4 and 14 in Islington; 3 and 10 in London City; 16 and 35 in Bethnal Green; 15 and 35 in St. Giles. The deaths from all causes on the north side of the Thames (1118) were 89 more than the deaths (1029) of the previous week. The parishes which have not yet been visited must be on their guard. Those in which the epidemic has partially subsided should redouble their precautions. The epidemic of 1832 broke out in three successive eruptions; the first commencing in February, was at its maximum in April and subsided; the second rose rapidly from June to July, and sunk again down to the second week of August; its course was very much like that pursued by the present epidemic. The deaths returned by the parish clerks in the three weeks from July 17 to August 7, in 1832, were 968, 793, 661; which, allowing for the defects in their returns, and for increase of population, are equivalent to 2323, 1903, 1586, or 5812 deaths in 1849, when the deaths registered in the corresponding weeks were 1931, 1967, 1909, or 5087 in the three weeks July 21 to August 11. A third eruption in 1832 broke out at the end of August, and extended to the first weeks of September; a fourth in 1833. It is satisfactory to find that the deaths of 819 out of the 823 persons who died last week of cholera are certified. They were seen by qualified medical attendants. But it is to be feared that the advice was not obtained in time. The accounts of the sudden stoppage of the epidemic by prompt medical treatment, and the house-to-house visitation, are perhaps over-coloured. But a mortality as high now as in 1832 should not take place: it may be prevented by improvements in the treatment, by arresting the premonitory symptoms, by still earlier attention to the general health. Medical men are called when the people are dying; but it is then too late. If the families of the middle and higher classes were seen at intervals during the epidemic by their medical attendants, and a corps of medical officers employed by the guardians to visit the poor at short intervals, the present epidemic might very probably be cut short, and a third eruption be averted. The precise locality in which almost every victim of cholera lived is given in the present return under each district; would it not be practicable for the authorities to have all these and the neighbouring localities inspected? If this were done, and proper precautions taken, the tragedies of Albion-terrace, Wandsworth-road, where seventeen persons died in two weeks in ten houses could scarcely recur. The particulars of the seventeen deaths will be found in the notes under Wandsworth and Clapham. Another case appeared this week in the note under Hampstead. In the house No. 6, Albion-terrace, five deaths had been registered—a Wesleyan minister's wife, aged 59; his mother, 90; a widow, 49; and two old servants. This is all we learn from the Clapham Registrar. The Registrar of Hampstead adds, that during the week, an aged man came with a friend to Hampstead for change of air,—breakfasted, dined, went to London to transact business at the Bank of England, and after his return seemed "pretty well." At six o'clock the next morning he felt ill, and had medical advice, but died in eight hours. This old minister was apparently the last of his family, for he had seen his mother, wife, and servants die before him in Albion-terrace, and could not fly from the poison which he carried in his breast. Such scenes of desolation could scarcely happen without great negligence on the part of the people themselves and on the part of the authorities.

MORTALITY TABLE,

(Metropolis.)

For the Week ending Saturday, Aug. 11, 1849.

Causes of Death.	Total.	Average of Five Summers.
All Causes	1909	1008
Specified Causes	1903	1005
Zymotic (or Epidemic, Endemic, and Contagious) Diseases	1182	302
Sporadic Diseases:		
Dropsy, Cancer and other Diseases of uncertain or variable seat	42	44
Tubercular Diseases	175	190
Diseases of the brain, Spinal Marrow, Nerves, and Senses	118	119
Diseases of the Heart and Blood-vessels	26	29
Diseases of the Lungs, and of the other Organs of Respiration ..	102	81
Diseases of the Stomach, Liver, and other Organs of Digestion ...	74	76
Diseases of the Kidneys, &c.	15	11
Childbirth, Diseases of the Uterus, &c.	4	7
Rheumatism, Diseases of the Bones, Joints, &c.	9	7
Diseases of the Skin, Cellular Tissue, &c.	—	2
Malformations	6	3
Premature Birth and Debility ...	32	23
Atrophy	38	25
Age	39	43
Sudden	8	8
Violence, Privation, Cold, and Intemperance	33	36
Causes not Specified	6	3

The following is the number of Deaths occurring from some of the more important special causes:—

Apoplexy	17	Heart	22	Phthisis	127
Bronchitis ...	34	Hooping-cough	45	Pneumonia ...	45
Cholera.........	823	Hydrocephalus	24	Scarlatina	21
Childbirth	2	Influenza	...	Small-pox	4
Convulsions...	43	Liver	17	Stomach	12
Diarrhœa	173	Lungs	7	Teething	6
Dropsy	12	Measles	21	Typhus	54
Erysipelas ...	10	Paralysis	22	Uterus	3

BIRTHS AND DEATHS.

	Births.	Deaths.	Deaths over Births.
Males	621	918	327
Females	638	961	323
Total......	1259	1909	650

METEOROLOGY OF THE WEEK.

Day.	Mean of Barometer.	Mean of Thermometer. Dry.	Ditto. Dew Point.	Difference between the Mean Temperature of the day and the same day on an average of 7 years.	General Direction of Wind. A.M. * In this Column, A stands for Active; N. for Negative; and P. for Positive.

TO CORRESPONDENTS.

Erratum.—In our last Number, in Dr. Routh's paper on "Transfusion of the Blood," 34th line from bottom, for a "free cut," read a "fine cut."

"Mr. Alfred Ebsworth, Bulwell, Notts."—Communication received.

"D. J."—We cannot account for the oversight. Dr. Stevens is about to publish a pamphlet on the Saline Treatment of Cholera. It is now in the press, and will contain the required information.

"Dr. Ryan's" pamphlet shall receive an early notice.

"Chirurgus" informs us that a full account of the treatment of Cholera by Camphor is contained in Dr. Knox's "Inquiry into the Present State of our Knowledge of Cholera."

"Cambria"—We think the surgeon can supply the medicine legally, and is not liable to a fine.

"Dr Fife, Newcastle-on-Tyne." — Communication received.

"Dr. Badeley, Chelmsford."—The request shall be attended to.

"Kappa."—The "Dublin Dissector" is a good work. The "Manual" referred to may also be consulted with advantage

"Mercurius" says, that Astro-Meteorology is a science, and when better understood will afford increasing knowledge of the laws by which epidemics are produced and regulated.

"Justitia."—We decline opening our pages any further to the controversy.

"Dr. Routh, Dorset-square," will see that his request has been attended to

"M. Gonderet, Paris," is thanked for the communications forwarded. In reference to the treatment of intermittents by dry cupping, our correspondent remarks, that M. Bouillaud has lately treated two cases successfully by this means at La Charité, and seven or eight at the Hôpital Necker, which it is his intention to place before the Academy of Medicine.

"Mr. J. Baker, Shirley, Southampton," having had experience in the treatment of Cholera, recommends the following plan:—"Finding fluids of every kind instantly rejected, I pulverized Ammon., Sesquicarb, Camphor, Opium, and Chalk, sufficiently powerful to excoriate the mouth and abrade the delicate membrane of the stomach By these remedies patients have recovered within twelve hours from the first attack, and, in some cases, the symptoms have abated in less than one hour. Infants have been successfully treated in this manner."

"Iago."—(1) We know nothing of the Assurance Office referred to. (2) Yes.

"Mr. N. B. Fisher, Bungay, Suffolk "—The delay has been unavoidable.

"A Subscriber, Portsmouth."—If a letter were addressed to the Author at Worcester, our correspondent would receive better information than we could possibly give him.

"S. J."—The patent Improved Horse-hair Gloves of Messrs. Lawrence, are well manufactured, and are very superior to the ordinary flesh brush. We have no doubt their judicious employment will tend to promote a healthy action of the skin.

"B. H. B" has forwarded a case of scirrhus disease of the os uteri, ending in cancer. The patient was a woman, 36 years of age for two or three years had felt uneasiness at the lower part of the abdomen, which gradually increased. The catamenia appeared regular till she became pregnant. As her pregnancy advanced, the pain became more acute, and it was greatly increased in walking, or on passing urine or fæces. No vaginal examination was at first made, but the patient was ordered a saline mixture with camphor and sp. æth nitr., three or four times a day; an injection of warm water per rectum night and morning, and the recumbent position. A mild sedative, also, to be taken at bed time. Under this treatment she at first appeared to improve, but subsequently the pain at the inferior part of the abdomen returned with increased violence. On making an examination per vaginam, around the cervix uteri were found three large tubercles, the size of walnuts, with several smaller ones, smooth like marbles. The strength of the sedative draught was increased, and, in a short time, the tubercles began to slough. A highly offensive discharge followed, to remedy which injections of warm water, containing chloride of lime and tincture of opium, were ordered three times a day. When the labour occurred, a still born child was expelled by a single violent uterine pain. The placenta followed in ten minutes. From the effects of the disease however, upon the woman's constitution, she only survived one hour after the birth of the child. Our correspondent has forwarded to us his name, which he does not wish published.

"Dr. S. M. Curl" has sent us a case of phthisis and scirrhus, in which the patient quickly recovered under the use of cod liver oil, and syr. ferri. iodidi. The patient was a married female, thirty-six years of age, in whom auscultation and percussion gave evidence of tubercular disease of the lungs. She had also a scirrhus tumour in the left mamma. She was ordered the following mixture:—℞ Sp. ammon. arom. ʒj.; tinct. digitalis. ʒj., ferri. citratis gr. xx.; t. cinch. comp. ʒij.; aq. distill. q.s. ft. mist. ℥iv., cap. coch. ij. med. ter. die. This she continued four days, when the hectic fever abated. The following mixture was then ordered:—℞. ol. jecoris. asil. ʒij ; syr. ferri. iodidi ʒiss.; inf. aurant. et. mucil. acaciæ, q.s. ft mist. ℥viij. cap. coch. j., mag. ter. die. The other mixture to be taken twice a-day, the dose of tinct. of digitalis being gradually increased. Eventually, the mixture containing only the cod liver oil was taken, and the patient in three months appeared in perfect health, and the tumour in the breast had nearly disappeared.

ORIGINAL LECTURES.

LECTURES
ON
OPERATIVE OPHTHALMIC SURGERY.
DELIVERED AT THE CENTRAL LONDON OPHTHALMIC HOSPITAL.

By H. HAYNES WALTON, Esq., F.R.C.S.,
Surgeon to the Hospital, and to the St. Pancras Royal General Dispensary.

LECTURE IV.

Extraction.—Description of the instruments required.—Positions of the patients and the operator.—Details of the operation, with a review of the several proceedings, and a consideration of the means of overcoming difficulties or accidents that may arise.

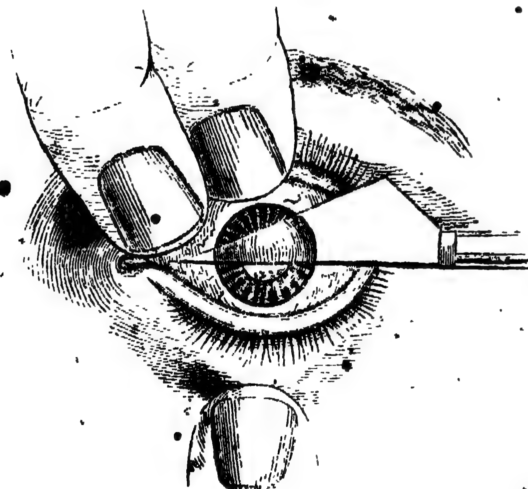
EXTRACTION.

Gentlemen,—Before operating I prescribe some purgative, and desire it to be taken sufficiently early, that its effects might end not later than the night previous; it would be very improper to allow the necessary quiet of the patient to be disturbed immediately after the operation by the action of medicine.

It is very problematical whether dilating the pupil keeps the iris more out of the course of the knife. At all events no disadvantage arises from the dilatation. The position of the patient, whether sitting or lying, is of little moment if he be quiet: but assuredly one who is restless ought to be on his back.

I divide the cornea in its upper part, preferring the upper section, as it is called, since it combines more advantages than any other. I always stand behind my patient, a superiority of position that cannot be over-estimated when the globe of the eye is the subject of operation. If want of practice, or deficiency of confidence, prevent you from employing the left hand, you will be obliged, when the left eye is to be operated on, to be in front, and, to make a lower section of the cornea, or else, by what appears to me to be a more difficult and uncertain proceeding, perform an upper section by cutting from you. It is remarkable that the left eye more frequently fails after extraction than its fellow. I have no hesitation in attributing the fact to the faulty performance of the operator, arising from the difficulty offered by that eye.

I shall confine myself to a description of my own practice, the principles of which are applicable to any method of corneal section. The instruments I use are two knives;—one triangular, a modification of Beer's; the other narrow and blunt pointed, and called a secondary knife, and a pair of scissors with probe points; and here you see is an improvement of the ever-improving Mr. Weiss. I allude to the eccentric or lever points, giving, it is said, freer motion, better leverage, and more of a drawing cut than the ordinary ones; the larger the scissors, the greater will be those advantages. A double instrument called a curette, one limb being of steel, slightly curved at the point and sharp; the other of silver, and formed into a sort of narrow spoon. A fine hook, when necessary, for withdrawing the cataract.



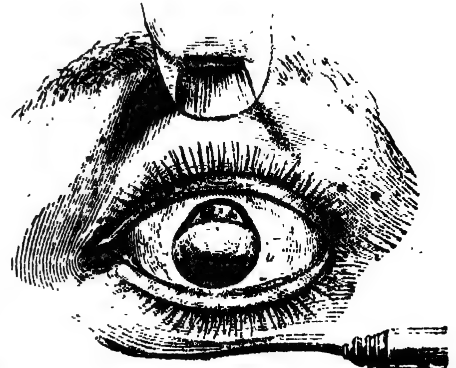
Now each of these requires a particular make and temper, but it would occupy too much time to enter into an individual description, and more unnecessary, since the able maker from whom they are obtained thoroughly understands what is required, and can supply you with fac-similes.

Should a sitting posture be chosen,—it is that I give the preference to,—the head, thrown backwards, should rest against the inclined back of a chair, one over which you should have perfect command (some surgeons may require a stool); the exact height is a matter of choice. I usually so arrange it, that when I am standing nearly erect the eye is on a level with my arm held at a right angle. With a less high chair, the head may rest against the operator's chest. With the patient in a lying posture, I still stand, and, therefore, require him on a high table, or with one of ordinary height; the head and shoulders must be raised by pillows, or some other contrivance. Some surgeons invariably sit to extract. The importance of a proper light is evident, and as I suppose that an operator would choose that which according to the arrangement of the room suits him best, any directions seem unnecessary.

It is customary to bind up the other eye if it have any sight. I object to the practice, because it possesses no advantage, and the formality tends to unnerve the patient.

The operation, well performed, is bloodless.

The first object is to make a cut of the cornea sufficiently large to admit the easy escape of the cataract. Suppose the right eye submitted to us, and everything arranged for commencing. An assistant should gently draw downwards the integuments of the lower lid, taking care that the globe be not pressed on, which may be avoided, by resting the finger employed on the malar bone. Very little retraction will suffice. The operator laying his left hand on the patient's forehead, with the fore-finger elevates, draws forwards the upper lid and locks it under the edge of the orbit; the tip of the finger should be below the tarsus, that it may be applied against the globe to prevent upward motion, while the middle finger is so placed on its inner side as to control any movements in that direction. The fingers should not encroach on the cornea, but be kept away from it as far as is possible.



I have supposed these preliminary steps easy of accomplishment, and they would be, were the eye to be directed forwards in the manner desired. It frequently requires much patience, gentleness, and management, to get it in that position in which it may be steadied. The nervousness of the patient quite disqualifies him for regulating its movements. With the globe well fixed, and the lids nicely retracted, troublesome part is overcome, especially if the eye be sunken, or the palpetral fissure small.

The right hand should rest against the side of the face, the thumb and two first fingers unrestrained, and allowed free play for the use of the knife, which should be entered at the central and external part of the cornea, about half a line anterior to the sclerotica, passed rapidly through the anterior chamber, and the point brought out on the inner side, at a spot as nearly as possible opposite to its entrance. It matters not if the external puncture be higher or lower than the centre of the cornea, provided that the counter-puncture correspond to it. As the globe cannot be kept stock still, without an injurious amount of pressure, it will roll a little during the introduction of the knife and its passage through the chamber. Great nicety is required to adapt the hand to the yielding, and without which you cannot make a proper counter-puncture. The remainder of the cut ought to be executed slowly, and with the same continued thrust or push of the knife, taking care so to direct the edge in its entire course that it shall pass at a uniform distance from the sclerotica. When the last portion is divided, a jerk may occur, but ought to be avoided, by proceeding particularly slow. I have found assistance from placing the end of the finger on the back of the nail against the last resisting portion, as a check or support

After the counter puncture, the globe is sufficiently under the operator's control to be made to resume a proper position, should it have rolled too much inwards.

The pressure with the fingers should be lessened as the knife advances, and entirely cease just before it is free; prior to which, also, the assistant had better relax his hold; after it is liberated, the upper lid should be gradually released and the eye closed. Subsequent to a brief repose, the lid should be again raised, but only sufficiently to expose the cornea, the patient told to look towards his feet, that the globe may be directed downwards, the curette introduced beneath the corneal flap, and the capsule lacerated. The cataract is now to be started by pressing on the globe with the finger that raised the lid, (I use its point as a wedge between the globe and the upper part of the orbit), and the curette placed on the outside of the lower lid; the force should be gradually increased till the opening of the lips of the cornea by the bulging of the iris indicates that the cataract has left its position. With a little patience the pupil dilates, and the cataract begins to appear externally, then all pressure should be remitted, for the elasticity of the cornea will suffice to expel it. The operation is now over.

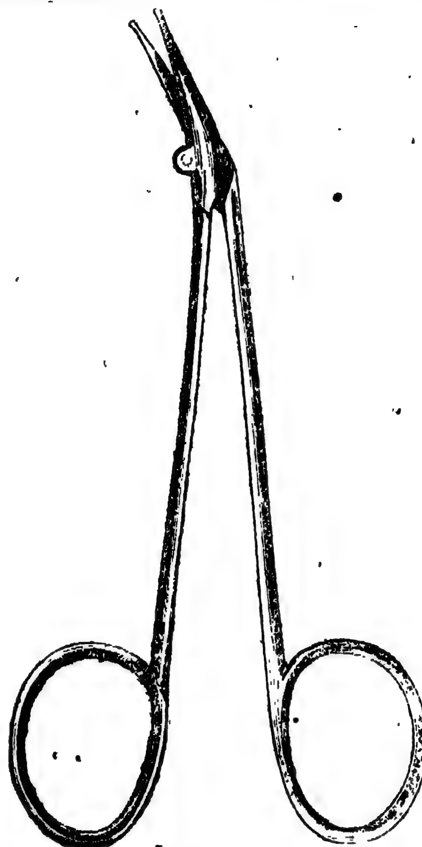
I shall review the various steps I have described.

If the cornea be divided as I have directed, there will be ample room for the cataract to pass out, but in proportion as it is smaller, will there be difficulty to its exit; and when it is under a certain size it cannot escape at all.

A faulty section may arise from entering the knife too much above the transverse axis of the cornea, or too far from the sclerotica, or having made a good entrance, the counter-puncture may be in the wrong place. Again, the cornea may have been admirably transfixed; but, the edge of the knife, instead of being kept parallel with the sclerotica, directed forwards, and made to cut its way out in an improper place. Either of these is equally bad; the most common, and therefore the most to be avoided, is an imperfect counter-puncture. It has been to remove that occurrence, that some ingenious, but worse than useless instruments, have been invented to keep the globe still.

I presume that you have learned, by actual experiment on the dead subject, what sized aperture is required for the easy escape of a lens, and that, having failed in making a proper one for the cataract, you will at once recognise your fault, and, without making fruitless and dangerous attempts at squeezing, resort to the proper expedient, which is, to use the secondary knife till proper space be obtained. This subjects you to a very nice proceeding. When the blade is introduced it must be kept well forwards with the end which is blunt against the cornea, that the iris be not injured. The cut, if possible, should be effected by a succession of outward strokes on the outer part of the cornea.

It is better to let the eye rest a little before resorting to this knife.



According to my experience, the average of failures in these cases is large, and I attribute it to the cornea being jagged, and the iris bruised and irritated. Some operators use scissors instead of a knife.

As bad as this secondary affair may be, it is still worse to force a cataract through a small aperture, for *a great* essential to success is its easy passage out of the eye.

The iris may get in the way of the knife in the first step of the operation, and produce difficulty, so that it would be impossible not to cut it were you to proceed. This occurrence is mainly attributable either to premature escape of aqueous humour, or from not keeping the knife well-adapted to the cut it is making, or what amounts to the same thing, wriggling or twisting it, and making the edges of the wound to gape, for, with the slightest aperture, out spirts the humour. It must be apparent, that I do not recommend any sawing movement with the knife; I strictly avoid it even when the smallest portion of the cornea remains undivided. With the same continued thrust should every part be severed.

If the aqueous humour escape before the counter puncture be made, withdraw the knife and delay the operation.

If the cornea be nearly divided, and a considerable portion of iris fall on the edge of the knife, withdraw it, and complete the work with the secondary knife, the blade of which must be passed under the remaining tag, and cut out by long strokes in whatever direction you prefer, or find most convenient. If, at any stage after the counter-puncture, a small portion of the iris be in the way, pay no regard to it; a small bit being shaved off matters little, especially if it be the margin of the pupil. If a piece be cut out of the iris, a second or false pupil will be the result; it is better, then, at the time, to divide the separating isthmus with the scissors, and make the two into one. In a few instances, the former accident has happened to me, but the latter never.

It is recommended, by high authority, always to attempt to free an entangled iris by pressing it between the cornea and the knife.

I have seen, under the hands of two eminent oculists, a small bit of the iris fall on the knife's edge; and, although both of those men tell us, in their books, how it may be extricated by pressure, neither attempted it, but proceeded as usual, allowing the iris to take its chance.

The fingers of the operator are so engaged that he cannot well shift them from their occupation to another purpose; and there would be such a want of consent between those of an assistant and his own, that in the majority of instances, if not always, the safer plan is to proceed and inflict a slight wound rather than attempt an extrication. I feel perfectly sure that some of the rules laid down on this head by writers cannot, with safety to the eye, be reduced to practice.

After the aqueous humour has escaped, the upper lid becomes wet, and is not so easily raised. If you wrap a bit of thin linen rag around the finger, the slipperiness will be overcome. The same plan may be found of use in other instances, when the lids are moist or wet from any other cause, lacrymation for instance.

The iris always bleeds when wounded; and the presence of blood beneath the cornea is likely to embarrass the young operator. It is soon absorbed, and need not occasion any anxiety.

The point of the curette introduced, with the concavity upwards, should be applied on the capsule, and then carried in any direction once completely across as far as the pupil will allow. That will suffice if the capsule be transparent; if opaque, and consequently tougher, it should be used more freely, precaution being taken that the pressure do not displace the cataract posteriorly; when withdrawing it the convexity should be upwards. If the point which is on the cataract be made the centre of motion when it is turned, the cornea and iris will escape injury.

If, after sufficient pressure on the globe, the cataract do not move forward, or evince some sign of displacement, and there be no discoverable impediment, you must resort to the hook, introducing it as you should the curette; pass the end behind the iris, and beyond the margin of the cataract, into the posterior surface of which plant its point, and cautiously draw the cataract up. The same practice must be resorted to when, with slight pressure on the globe, the vitreous humour rises up by the side of the cataract; and here even greater care is required, from the vitreous humour being unhealthy and preternaturally fluid. Rough fingering would cause much of it to be lost. If, in attempting to use the hook, the cataract gets displaced, still try to secure it, if it be fairly in view. Very recently I had a case with the vitreous humour so fluid (and I may here remark that it is not always possible to know this beforehand, for in this instance the globe was neither boggy nor unnaturally hard), that, with slight pressure, it escaped, leaving the cataract unmoved, and which, when touched, floated immediately in the vitreous humour. By patience and manœuvre, I got it out. Had it passed out of sight, or not been caught after a moderate trial, I should have left it alone. I have somewhere read of an operator *fishing* for three quarters of an hour for a sunken cataract, and at last *harpooning* it.

But the more common case is, that the cataract attempts to escape, and is prevented by the external opening not being sufficiently ample, by adhesions of the iris, or an unbroken capsule. I have told you how to obviate the first. Whenever the cataract passes partly through the pupil, and stops at the lips of the cornea, you may be sure that more room is required. If adhesions be the cause, the iris will bulge forwards, the cataract not being able to pass through the pupil because it cannot sufficiently dilate. If you were ignorant of adhesion before operation,—a most inexcusable omission, you may be puzzled to discover its exact locality. When found, it should be divided with the scissors. The correct course is to ascertain the point beforehand, and to divide any adhesions prior to the curette being used.

An imperfectly lacerated capsule is recognised by the pupil expanding, the iris passing forwards, and the cataract not escaping. The curette must be more effectually applied.

While the cataract is emerging from the cornea, it may fall in several pieces; some of which may remain between the iris and the cornea, or the external or soft parts may not escape with the harder portion. What is to be done in such cases—the latter of which is very common, and often to be attributed to an insufficient outlet? Attempt with the spoon of the curette to remove any hard fragments, except they be in the pupil, when interference is wrong. The same rule applies to the soft matter, with the exception, that should merely a little of it remain, do not subject the eye to further disturbance unless the adaptation of the corneal flap be interfered with; soft lenticular matter is soon absorbed.

The iris does not always recover itself after the cataract has passed the pupil, but protrudes and is unmanageable. If after gently touching the globes through the closed lids, and waiting a little, it fail to assume its wonted position, try to return it with the blunt end of the curette, and again rub the globe; should this also be useless, Mr. Tyrrell advises a small portion of the vitreous humour to be evacuated. I have never had to resort to such an expedient, nor ever would.

The most troublesome cases of prolapsed iris are those complicated with the presence of the hyaloid

membrane in the wound. When that membrane alone protrudes, make an attempt to return it, and should that fail, as a last resource cut off with scissors as much as hangs out. I should not meddle with the iris; from what I have seen I should prefer leaving it alone; I think that the cases in which it is cut are not ultimately so favourable as those that are left untouched.

Whenever the vitreous humour hangs out, and keeps the lips of the cornea open, you may be sure that there is hyaloid membrane along with it. The flap of the cornea requires to be looked to; it may turn downwards, or, losing its convexity, fall in; in either case union could not be effected; the use of the curette will remedy these conditions. I am sure that when the vitreous humour is unnaturally fluid, no operative skill can prevent its partial escape, and eyes do well in which a small quantity of it has been lost, *i. e.*, they recover vision. I have not instituted any inquiry of their equal success with those in which all has been retained. That a small loss of it cannot be beneficial, as some have reported, I feel certain. An amaurotic state does occasionally accompany the escape of any quantity, as I can testify from my personal knowledge. As a principle, endeavour to prevent it. When once it has commenced to run out, very slight circumstances will occasion a further discharge, and I have mentioned the disadvantage of the hyaloid membrane accompanying it, a circumstance always to be dreaded. Authors undertake to tell the effect that will be produced on vision according to the amount lost, and speak of a third, or a fourth, or a fifth. All this is mere conjecture; how is one to decide on the quantity?

But the vitreous humour may be actually forced out by the operator's fingers at some step of the operation. Pressure enough to control or direct the motions of the globe, or displace a cataract with a healthy vitreous humour, is never injurious, but beyond that, danger is at hand. It is a common accident with beginners, for the cataract and some of the vitreous humour to burst out directly that the cornea is divided. Spasmodic action of the muscles of the globe generally bears the blame. I have heard of the point of a knife being broken while passing through the cornea by muscular action! If, as I have shown, we do not always know what state of vitreous humour we are to encounter, whether healthy or not, we must never be off our guard, but ever careful and cautious.

I have deferred the few following remarks till after describing the operation, thinking that they will be better appreciated.

Subsequent to the middle period of life, the cornea is prone to become flattened and smaller, the anterior chamber consequently reduced, and should there be less space than the knife could be used in, without wounding the iris, extraction should not be attempted.

The same rule is, of course, applicable with diminished capacity of the anterior chamber from a bulging iris, the cause of which is posterior pressure. Entire adhesion of the pupil to the capsule of the lens, likewise forbids extraction, but partial adhesion can be overcome. Now, out of this a very practical question arises, With what amount or extent of adhesion may extraction be undertaken? Theoretically, it is most difficult to give an answer. I can only say, that whenever extensive use of the scissors would be required for the liberation of the iris, a successful result could scarcely be expected. The most fortunate termination would probably be, a closure of the pupil from consequent inflammation, and a chance, at some future period, of an artificial one being made.

Adhesion of the iris to the cornea may forbid extraction, either from its extent, or the part of iris implicated; but, if merely an inconsiderable marginal portion were adherent, I should not hesitate to divide it during the section of the cornea, provided I could so direct the course of the knife that the rest of the iris would escape injury. But there may be a previous operation for the purpose. A small clear cut of the iris with a keen-edged knife during the section of the cornea is, in after consequences, a much less objectionable measure than is supposed; indeed, it is scarcely comparable with the more injurious use of the scissors, the only admissible instrument for the division of adhesions, in the flabby and unmanageable state in which the iris is found after the escape of the aqueous humour.

[The wood-cuts which illustrate Mr. Walton's lectures are original sketches by Dr. Westmacott, of King's College.—Ed. *Medical Times.*]

SCARLATINA, SUCCESSFULLY TREATED BY HOT-WATER APPLICATIONS.

By F. A. BULLEY, Esq., F.R.C.S.,
Surgeon to the Royal Berkshire Hospital, Reading.

Mr. Thomas S., a respectable farmer, residing near this town, of ruddy complexion, tanned and freckled by much exposure to the sun, and who had, generally speaking, enjoyed the best of health, had complained for several days before I first visited him of a swelling and soreness of the throat, which had occasioned him great uneasiness. For three or four days he had been unable to swallow anything, even of the most liquid kind, without difficulty, with an entire loss of appetite, feeling very heavy and sleepy, and complaining of a dull, aching, overpowering sensation in his head. These symptoms had continued to increase until Tuesday, July 10, when his family becoming alarmed about him, thought it necessary that he should undergo some medical treatment, especially as on the previous evening they had observed a peculiar rash, making its appearance on different parts of his body.

On examination, the following appearances presented themselves, which, taken together, left me little reason to doubt that the disease under which he was suffering was scarlatina of no very gentle nature, and would require no little activity in the treatment to prevent its lapsing into its most malignant type.

On examining the throat, I found a swelling on each side, externally, perceptible to the sight, and exceedingly painful on pressure; internally the tonsils were so greatly enlarged, as by their approximation almost entirely to prevent the passage of food between them, and were of that peculiar dark purply colour, characteristic of the gangrenous tendency which sometimes accompanies this disease in its severer attacks; this discolouration was also observable on the return of the palate and uvula, which latter was considerably enlarged, and the whole of the inflamed surfaces were covered with a viscid and adhesive mucus; there was, however, no particular ulceration anywhere, except just in the centre of the right tonsil, where there was a slight superficial abrasion of the surface; the skin over the whole body was dry and harsh, and had a burning feel in every part, but especially over the surface of the abdomen, where the heat was most intense; there was not the slightest appearance of moisture on any part of the body.

In different parts of the body, but more particularly over the chest and abdomen, the characteristic eruption of scarlatina had completely displayed itself; over the legs and arms it was rather faint and in patches, whereas upon the trunk it was continuous and of the bright red colour distinctive of the nature of the disease.

His tongue was fissured, parched, and red at the edges, with great thirst and constant longing for small beer. Pulse 120, moderately strong, with a palpitating struggling action of the heart; he complained of great pain in his head, and the feeling of constriction in his throat was such that he thought himself to be in imminent danger of suffocation.

For this apparently unfavourable combination of symptoms, the following simple, but active and as it turned out, successful treatment was adopted. The patient was placed upon a bed, on which, the sheets having been removed, two blankets had been laid, then a flannel pad, composed of four thicknesses of coarse household flannel, 16 inches long by 10 inches wide, stitched round the margin to keep it together, and wrung out of hot water till almost dry, was laid as hot as he could bear it upon the pit of the stomach and over the region of the heart; and while it was still warm, the blankets, one by one, were carefully folded round his body, so as to completely confine the perspiration and heat, which might be generated by this process; at the same time, another pad of two thicknesses only of the coarse flannel, wrung out of boiling vinegar and water, was placed round the throat for the relief of the local inflammation. After he had remained enveloped in the wrapping a little more than half an hour, during which time the febrile excitement had been somewhat increasing, he burst into a profuse and general perspiration, in which he was allowed to remain for two or three hours longer, with an evident abatement of the symptoms, when the blankets were carefully removed, and the flannel pad withdrawn; after this, he had some refreshing sleep, and but little return of the burning fever; he was now ordered to take half a drachm of Dr. Stevens's saline powder in a mixture every four hours, and to use the following gargle to the throat:—

℞ Armenian bole; burnt alum powdered, aa. gr. 40; brown sugar, gr. 60; water, ℥viij. Mix.

July 11th, next day.—Has passed a tolerably comfortable night; the inflammation of the throat is greatly diminished, and he has lost the agonizing pain in swallowing, which he can now do with comparative ease; skin uniformly moist, and the laborious action of the heart has in a great measure subsided. The eruption continues, but is not so vivid as yesterday; to have strong beef-tea strongly flavoured with salt. The body was sponged in the morning with tepid vinegar and water; and in the evening, the fever having slightly returned, the hot padding was repeated, but not for so long a time as yesterday, as the perspiration was more easily induced, and the fever was readily subdued. After this period he had no further return of the fever.

12th.—The swelling of the throat has entirely disappeared, as well as the redness, and he now swallows without pain. No return of the fever; the eruption is beginning to decline; a gentle moisture, assisted by warm clothing, continues on the skin; his natural appetite for food is returning.

14th.—He sat up in his bed-room to-day for the first time, feeling, however, somewhat weak; the efflorescence of the skin has subsided, and the cuticle is beginning to peel off from different parts of the body; his appetite and power of swallowing has so far returned, that he is able to eat a mutton-chop with a relish, and without pain.

16th.—Although extremely weak, he appears to have lost all traces of the fever; his appetite has completely returned, and he is gradually gaining strength, so much so, that I told him he might go down stairs for the first time to-morrow. The saline mixture which he has taken every four hours, up to the present time, is to be discontinued, and a mixture composed of the infusion of chyraitta, with cascarilla, ordered in its stead. A day or two after this date, seven days from the first appearance of the eruption, I found that he was out of doors somewhere about his farm, but I understood that he was fast recovering his strength.

Observations.—I have related this case with a view to illustrate a peculiar mode of treatment, which I have adopted and found successful, not only in this particular kind of fever, but in every other instance of either active or passive febrile disturbance which has within the last few years come under my observation.

It would be beyond the intention of this communication to speculate upon the pathological origin of fever; but it appears essentially to consist of a series of conservative efforts of nature to relieve the system of some pervading noxious influence—some animal poison abiding in the blood, which, if unassisted or ineffectual, at least are followed by an alteration of that fluid from its natural healthy composition, to such an extent, as to render it incapable of further maintaining the healthy vital functions.

It must be obvious to every one who has paid

any considerable attention to this subject, that, in almost every kind of fever, of whatsoever type or nature it may be, the skin during the time of its continuance has lost its natural functions, its healthy depurating office appears to be suspended or at any rate greatly disturbed; and this may almost be taken for granted, when we reflect upon the great number of diaphoretic remedies with which the Pharmacopœa abounds, and which, under this impression, are constantly called into operation in the treatment of febrile diseases.

But it cannot be doubted, that the effects of such remedial agents as are commonly designated diaphoretics are in some cases injurious, in all, uncertain and evanescent. The various preparations of the tartarised antimony are of this class; but, as everybody knows, they not unfrequently nauseate the stomach, impair the appetite for food, and diminish the circulating power, and in this way manifestly impede the natural actions of the body to relieve itself of its disease; and the same may be said of opium, and its various medicinal preparations, and many other remedies of the same description; they appear, from the debility which they sometimes induce, to act rather by producing a passive cutaneous exudation, through a diminished action of the heart, than the healthy flow of the sensible perspiration which follows an increased activity of that organ, as we observe in all the diseases of debility, in contradistinction to those which occur in persons whose circulating power is strong and vigorous, where the perspiration affords relief to the symptoms, especially those of febrile congestion and excitement, whereas, in the opposite state of the circulation, no such good effects arise.

Arguing upon these, to my mind, well-established facts, I long ago considered that it might be possible, by the application of heat and moisture over the region of the heart, and, as nearly as might be, over the peripheral extremities of the ganglionic nervous system, assisted by the method of blanket-packing which I have described, to produce such a manageable excitement of the general circulation as would end in a complete action of the skin, without the necessity of taxing the stomach alone for a very round about and uncertain result.

I have had the satisfaction to observe, that the simple method which I have adopted in the treatment of fever, and which I practised in the foregoing case, has never, in any trial which I have made of it, failed in its object. I have now used it in a great number of cases, some of them of the worst description, and in every instance where the process has been judiciously managed, it has either at once annihilated the fever, mitigated its severity, or diminished its duration. I have also found it extremely useful in cases of small-pox, in constitutions where the circulating power has been naturally so feeble as to be insufficient of itself to throw out the morbid elements from the blood by the skin, and I hope shortly to be able, through the pages of this Journal, to introduce several of the cases which I have treated in this manner, to the notice of the Profession.

The natural progress of an active fever is accurately illustrated by the different phases of an intermittent, the cold stage or that of collapse, being succeeded by the re-active or hot stage, which, after a certain period, longer or shorter in different individuals, according to the natural power of the circulation, is followed by a more or less profuse perspiration. As soon as this latter stage is perfected, the urgent symptoms of the disease subside, at least for a time; the patient feels in comparative comfort; and it would certainly appear that something had been thrown out of the system through the skin and the other emunctories which had been exerting an injurious influence on the organism, and which absolutely required the febrile paroxysm for its removal. But this effort of nature is in most instances insufficient of itself to separate the whole or even the greater part of the poison from the blood; for we generally observe, that after an uncertain period, after the powers of the system have had time to recruit themselves, another paroxysm of the same kind occurs; and these being frequently repeated, until at length none of the materies morbi remain, the efforts of nature are no longer required, and thus the fever ceases.

It has struck me that, in the treatment of these diseases, it is a rational mode of practice to attempt, by the artificial production of a speedy perspiration, the acceleration of the cure, seeing how great is the relief which the natural process, even when imperfectly performed, affords. But it has been objected by some eminent authorities, especially of the old school, that induced perspirations are injurious, as being productive of such an amount of weakness as would lessen the chances of ultimate recovery; and such is probably true as respects the use of internal medicines, of themselves debilitating in their nature, but cannot hold good as regards the repetition of hot water to the skin for the same purpose, which, as it favours a more continued escape of the sensible perspiration, renders the frequent repetition of the febrile paroxysm almost unnecessary. It is the intensity and continuance of the febrile paroxysm, as a whole, and not the perspiration as a part, to which the debility has been by some, somewhat unjustly, attributed.

It is difficult to understand, exactly, the action of water applications in their effects upon the skin, in febrile disorders. Dr. Currie, of Liverpool, who has the credit of introducing the practice of cold water affusion in fever, and particularly in scarlatina, and which he practised with considerable success, thought that the results of the processes which he employed were due simply to the re-action of the capillary system, induced by the shock of the cold water thus applied upon the surface, whereby the blood which was circulating in the capillary vessels, during the hot stage of the fever, and struggling, as it were, to discharge its morbid elements through the cutaneous exhalents, was suddenly driven back to the heart and larger blood-vessels, which, being thus suddenly called into action, acquired a superadded vigour equal in most cases to the emergency, and by virtue of this increase of the propelling force, drove the blood again to the surface, and thus produced such an amount of increased capillary activity, as ended in their relief by perspiration, when the balance of the circulation was restored for the time; perhaps, also, the application of the water to the dry and burning surface might, by softening the skin, and clearing the openings of the sudoriferous ducts, have facilitated the production of the sweat; and this would appear to be true in some cases, where we observe the same effects to be produced by tepid ablutions.

But it would seem, that, over and above the simple effects of re-action of the capillary system, something may be due to the power of water as an efficient electrical conductor, and that, if there be any truth in the modern hypotheses respecting the influence of some particular electrical conditions of the atmosphere, in producing diseases of the body, resulting probably from a loss of the proper balance between them, water acts, by its conducting quality, in facilitating the restoration of the lost balance, either by allowing the more easy transmission of electricity into the body, the atmosphere being plus and the body minus; or, on the other hand, its more easy escape from the body, the body being plus; for, it cannot but be supposed, that, if these theories be true, the body would be at different times in these different states of electricity, which might be productive of different kinds of diseases.

Whether either of the foregoing theories of the action of water-applications in fever approach the truth or not, the method which I adopted in the case related, cannot be said to have acted altogether in either manner; I will endeavour, however, briefly to explain what I think to be its *modus operandi*. It will be observed, that the thick flannel pad, wrung out of the water, was placed as hot as it could be borne over the situation of the heart, and extended for some distance over the surface of the abdomen, and that the whole of the body was afterwards carefully wrapped in blankets, and a large quantity of extra clothing subsequently laid upon the bed. It was presumed, that by thus disposing of the heated pad, it was in the nearest possible contiguity to the circulating organ and the peripheral extremities of the organic nerves spread over the intestines; that the impression of the heat upon these latter was conveyed to the ganglia of the sympathetic system, and by a kind of reflex action to the heart, whereby its circulating activity was increased, enabling it to propel the blood with a greater force to the surface, and thus activity was probably assisted by the contiguity of the heated pad over the situation of the heart itself. The blanket wrapping, which, by excluding the cold air, prevented what is technically called the spasm of the skin, and, by preventing the evaporation of the insensible cutaneous exhalation, favoured the production of the sweat.

The want of space prevents my speculating at large upon the particular effects of the water application in the foregoing case; I can only say, that it acted like a charm. The sudden subsidence of the intense inflammation of the throat, and subsequently of the cutaneous efflorescence, lead me to believe, (from what I have been able to observe in this and similar cases,) that the poison of scarlatina resides essentially in the blood, which the skin, rendered entirely inactive and useless for the purposes of the economy, by the early occurrence of the pervading inflammation, is incapable of ridding it of, except when assisted by some such means as I have described; and it is probable that the mucous surfaces of the air passages and intestinal tube are similarly circumstanced to the skin. What wonder, then, is it, that the glandular system should suffer from the excessive action into which it has been suddenly called, by the necessity imposed upon it of separating from the mass of the blood those deleterious constituents which the skin seems utterly incapable of separating, and that the destructive disorganization of the tonsils, and the granular degeneration of the kidneys, which sometimes occur, should be the result of the excessive congestion to which they have been thus exposed.

The success which I have observed to attend these means of affecting the capillary circulation in fever has led me to employ them in restoring the diminished temperature of the body in a few cases of cholera, which have lately come under my observation, and in no instance, even in one of extreme collapse, have they failed to induce a complete re-action, with the cessation of the spasm, the usual result of a return of the healthy function of the skin through the circulating system. They have, of course, been combined with such other means as would simultaneously act upon the congested ganglionic-nervous centres, upon the integrity of which the healthy vigour of the circulation may be mainly said to depend. This auxiliary treatment has consisted of the exhibition of moderate doses of the essential oils, frequently repeated, especially of the oils of clove and aniseed, both of which are known to be capable of relieving spasm, by stimulating the nervous system of the digestive organs, and thus relieve the congestion under which they are suffering in this disease, and, in this way, secondarily aid the general restoration of the circulating power. In these cases, I have employed the hot water applications rather more extensively, the pads having been applied all over the abdomen and down the thighs, to encourage the returning circulation.

I trust I shall be excused, although digressing from the proper scope of this communication, if I venture to make a few observations on the pathological nature of cholera, which, like many others that have been advanced of late, may either be wholly hypothetical, or, on the contrary, may be worthy of such a small degree of attention as may lead to further investigation. I believe cholera, as it is now displaying itself with such fearful virulence in this country, to consist essentially of a congested condition of the organic nervous centres, and in some measure of the spinal cord and its investments, these conditions varying in intensity and degree, according to the intensity and power of the exciting cause. I believe, also, that this congested, and perhaps paralysed, state of the ganglionic system, induces the unavoidable interruption of the functions of every organ which is dependent upon this system for its regular and healthy action, and that these portions of the nerv-

ous system are in this disease more particularly affected than the brain. I will endeavour to prove —1st, Negatively, because, in the majority of cases, the intellectual faculties are observed to be from the first, clear and unaffected, and, in many cases they remain so to the last; of course, as the disease approaches the fatal termination, the cerebral functions become clouded, and coma ensues, from the circulation of poisoned or imperfectly depurated blood through the vessels of the brain, or, what is as probable, by the absorption of urea, occasioned by the suspended action of the kidneys, which frequently occurs only towards the end of the complaint, and constitutes one of its most fatal symptoms. 2nd. Positively, because, from the very onset of the disease it is observable, that while the sensory functions of the brain are, at least in the early stages, apparently unaffected, the functions of all those organs, which are dependent for their healthy action upon a normal condition of the ganglionic centres, are from the very commencement of the malady, interrupted, or perhaps entirely suspended; the heart, liver, stomach, and intestinal canal, and, indeed, all the apparatus of organic life, are affected with a more or less complete suspension of their action; and it is not till this particular portion of the nervous system is relieved of the congestion, or whatever else it may be labouring under, by the general restoration of the circulation, that the affected organs recover their proper tone. The spasm then generally ceases, for, considered as a salutary action to restore the disturbed balance of the circulation, it is no longer required,—the diarrhœa is diminished, the healthy action of the kidneys is restored, and the disease may be said to be removed, provided always that the means which have been used have not been too violent or beyond the actual necessities of the case, in which instance the reactive fever would be excessive, a sequence as much to be dreaded as the disease itself.

Unfortunately, the records of Pathological Anatomy have shed but a small light upon the actual nature of this dreadful pestilence, but as partially corroborative of the views I have entertained respecting its most probable locality, I shall be excused for quoting the following passage by Dr. Brown, an eminent authority on this subject* :—"In one case only in India was the state of the spinal marrow examined, and in that, strong indications of inflammation were detected in its sheath; the case, however, was in some degree a mixed one. But Dr. Keir found at Moscow the blood vessels of the vertebral column and spinal cord loaded with blood, which was sometimes effused between its arachnoid and dura mater; partial softening of the spinal cord was sometimes met with, and marks of inflammatory congestion in the large nerves were detected. The dissections performed in Sunderland generally furnished results corresponding with those obtained elsewhere." It does not appear, from what I have been able to learn, that the ganglionic system has ever been made the subject of minute investigation in this disease, but it is not altogether improbable that, from its contiguity to those parts which, according to the above distinguished physician, are actually known to have been the subject of morbid congestion may have been affected in the same manner, but escaped the vigilance of the observers.

I would treat a case of collapse from cholera precisely in the same manner as I would treat a case of suspended animation from drowning. I would turn my whole attention to the best method of restoring circulation of the body and the healthy action of the skin, pursuing such means as I thought most likely to effect this end; and I should consider it quite as great an absurdity and loss of time to attempt to relieve the sickness and suppression of the urine which often occur in the latter case by internal remedies alone, as to endeavour to restore the action of the liver and other organs whose action had been suspended in the former; I should consider that I was labouring in vain to control symptoms which were depending upon a manifest temporary suspension of the circulating functions, and which could not rationally be expected to be removed until these functions were restored. Certainly, I would administer brandy in the one case, and the diffusible stimulants in the other, but only for the general object of assisting the restoration of the circulation. I would not waste time in endeavouring to check the diarrhœa, which is nothing more than the result of the spasmodic condition of the alimentary canal dependent on the general congestion, squeezing out of the blood its serous, and in some cases its fibrous elements, which, mixed with the chyle previously to the attack contained in the small intestines, appears in this disease to constitute the true nature of the discharges. I would persevere in my efforts until all reasonable hope was lost, the main and principal object being the restoration of the animal heat, which I would endeavour to effect, as I have already in several cases effected it, by the simple means I have suggested.

* Cyclopædia of Practical Medicine.

DIFFICULT MIDWIFERY CASE—FŒTAL DISFIGUREMENT.

By WILLIAM HOLT, Esq., Bromley, Kent.

On the 19th inst., at one p.m., I was requested to visit a young married woman, aged 27, who was reported to be in strong labour with her first child, at the 7th month of pregnancy. The patient was a healthy-looking person, and had borne the effects of pregnancy as well as women in general. She had been in pain since seven a.m.; the pains were strong and frequent, and there had been a considerable discharge of fluid; the uterine tumour, also, had subsided a good deal. On making an examination, the presentation appeared to be the arm; but, on tracing it up towards the trunk, I felt a large, soft, fleshy mass, apparently attached to it, the shape and dimensions of which were much more like the breech than the shoulder. Still, I became convinced that it was the arm which presented, and following the usual practice in similar cases, I decided on turning without loss of time. The difficulty of introducing the hand into the uterus was not much greater than usual; I succeeded in reaching a lower extremity, but all I could do was to get a finger into the groin. Such was the elastic force of this fleshy mass, which blocked up the os uteri, that all my efforts to bring down the extremity were foiled, and I was obliged to desist. I was at a loss to conjecture what this substance was; it could not be the breech, as the lower extremities were found in the usual situation, in arm presentations; from being in connexion with the arm, I should have supposed it to be some part near the shoulder, but its softness, elasticity, and great distension, made it feel much more like a part of the abdomen. Still, the absence of the funis rendered this improbable. The alarm and severe pain endured by the patient had the usual effect of diminishing the uterine efforts; it appeared necessary, therefore, to rest awhile from all further attempts at artificial delivery. I now tried what could be done by simply pushing back the arm, having succeeded, some months since, in a case of hand presentation at the eighth month, in this way, without turning; in the present case I had not so good a chance, as the os uteri was completely obstructed by the soft tumour above mentioned; and so it happened that, although it was easy to push the arm back, it was invariably forced down again by the uterine efforts. Some may think that it would have been better to have tried this plan in the first instance; but the fœtus here appeared to be very little below the usual dimensions, independently of the tumour, and I believe any accoucheur, taking all things into account, would have felt that turning alone presented a fair chance of putting the case right. Not wishing to be altogether foiled, I took advantage of an accession of stronger pains to make a second attempt at turning, but was again disappointed, and, as it appeared, solely by the fleshy excrescence lying at the mouth of the uterus. I now felt serious doubts whether this difficult and embarrassing case could be successfully terminated without embryotomy. A good deal of the cuticle had exfoliated from the hand; I concluded, therefore, that the fœtus had perished; this removed all scruples on the subject, and I went down in order to send for my son to come to my assistance. While I was waiting down stairs till a proper messenger could be found, the attendant called me up rather hastily, as the pains were now very severe. On carefully comparing the size of the fœtal mass with the pelvic dimensions, and taking into account the soft flexible character of the former in its inanimate state, I was resolved, if possible, to avoid the disagreeable office of fœtal dismemberment, by bringing down the whole mass in the order, or rather state of disorder, in which the parts were now placed, making use of the arm as a purchase, whereby to bring down the other members of the fœtus. I, therefore, applied a napkin just above the hand to give me a firm hold; and after a while, by steady and persevering efforts, I succeeded in bringing down one part after another, till, at last, there was nothing to deliver but the head. One or two energetic pains brought down this, and the birth was now complete. The placenta came away easily. The patient has continued to go on very well, and is now convalescent. It appeared that there was a soft bag of cuticle as large as the double fist projecting from between the shoulders of the fœtus over the cervical and some of the dorsal vertebræ. It was not much unlike a case of spina bifida, but, on close examination, the spinous processes could be detected, and, indeed, it wanted some of the other marks of spina bifida; in fact, it was simply a case of great fœtal disfigurement. The mother attributed the death of the child to a severe fright she had about a month before delivery. During the earlier stages of pregnancy she had been often frightened by toads; and if I were to assign any reason for the cuticular disfigurement of the fœtus, I should think the sight of so disagreeable a reptile, acting on a susceptible imagination, might cause the squalid appearance which characterised not only the shoulders, but the whole frame of the fœtus, more or less. I have several times seen very strange effects produced on the fœtus by the mother having been suddenly shocked at the sight of a toad.

In giving publicity to this case, I do not for a moment doubt the necessity of turning in almost every case of arm presentation; the practice is sanctioned by universal approval. The case is recorded to show that there may be instances where turning is impracticable, or unusually difficult, in which the painful and disgusting process of embryotomy may be avoided by following the dictates of our own judgment, not being blindly guided by precedent, but accurately comparing what requires to be done with the means there are of accomplishing it, and deciding accordingly. In this way we may sometimes be able to bring down the parts exactly as chance may have placed them. In this sense I have thought the case worthy of record; and will now, without further remark, leave it to the perusal of my professional brethren.

CHOLERA ASIATICA.

By WILLIAM ABBOT LAKER, Esq., London.

The premonitory symptoms of Asiatic cholera are profuse diarrhœa, with prostration.

Professional assistance is, however, too often deferred till the disease has arrived at the stage of collapse, when the following symptoms generally present themselves:—The patient is prostrate; his countenance pale; features shrunk; eyes sunken; cheeks fallen, the parts about the eyes and mouth dark; lips purple; tongue purple, red, or brown; cold and tremulous; the whole visage ghastly. On further inspection, we find the whole of the body pale, diminished in bulk; the extremities livid, contracted, and shrivelled; nails blue; the body exhaling a peculiar fœtor; respiration shallow, frequent, and anxious; voice small and husky, in some cases almost or entirely lost.

By examination, we ascertain that the skin is cold, harsh, and constricted; the pulse very small, feeble, and quick.

The patient exhibits apathy, but replies rationally, complaining of severe spasmodic pains in the lower part of the trunk and abdomen, and cramp in

the thighs and legs. The chief pathognomonic signs, however, consist in the evacuations, namely from the stomach of a limpid, semi-transparent, greenish yellow fluid, jerked up at frequently recurring intervals without effort; and from the bowels of a peculiar whitish liquid, without bile or fecula, resembling water in which rice or soap has been boiled; while the passage of urine is altogether suspended.

After death, the lividity, previously observed passes off, but is now frequently to be found on the under surface of the body, which is more than usually rigid. Removing the integuments from the sternum, the muscular tissue that is divided and exposed is perceptibly dark and dry. Proceeding, we observe little or no change in the general aspect of the contents of the thorax and abdomen, except that the intestines have a rosy hue, frequently arborescent. When the sanguiferous viscera are excised, we find that they are filled with dark, thick tar-like blood. In the stomach and intestines, we discover a quantity of fluid similar to those evacuated during life. The urinary bladder is contracted and empty. The contents of the encephalon exhibit no change. In short, the *post-mortem* examination generally terminates in the manifest disappointment of the anatomist, who fails to detect any structural change sufficient to account for death, or to explain a disease which has run its course with frightful rapidity; proving interesting and instructive on this very account, rather than from what is actually revealed. To my mind, indeed, the investigation is perfectly satisfactory, being well assured of the propriety of here adopting the sentiment "*de non apparentibus, et de non existentibus eadem est ratio*;" and persuaded that the occult cause which eludes the senses is to be deduced by reason, in the consideration and comparison of known facts and phenomena, on physiological principles.

There are two principles essential to life, or two causes which, by mutual antagonism or combination, produce the effect—vital motion; one stimulation, the other stimulability;—analogous, though not identical, with electricity, positive and negative; neither of which is sufficient of itself to produce or maintain motion; the former diffused by the sanguineous system, the latter by the nervous. The blood being tangible and cognisable to the senses, while the nervous fluid is probably ethereal and extremely subtile; presiding over and regulating all the functions of the animal economy, as might be well illustrated by a consideration of hyperæsthesia and its correlative anæsthesia, as vulgarly practised through the medium of the stomach in inebriation, and scientifically through the lungs in inhalation.

It follows, then, that the harmonious operation of these two systems is essential to vitality; and when we have to deal with its partial negation in disorders not structural, we have mainly to consider which circulation is chiefly at fault, and this we may ascertain by referring the impaired function of organs to one or the other, according as we find their influence, first or chiefly abnormally exalted or depressed; or, as we find certain functions affected which we know to be performed by individual organs more particularly united by one, or a branch of one, or the other system, the other system, or other parts of the same, being not implicated, or only so in a minor and subordinate degree.

Now, let us apply these tests to Asiatic cholera. The *sectio cadaveris* demonstrates that no appreciable structural lesion has taken place, as either cause or result of the disease, but that it is purely a disorder of function. The mode of the attack, and the course of the disorder are such as to afford a presumptive evidence that in this, as in a very large class of diseases, the nervous circulation is the one primarily affected, and that the change in the circulation and condition of the blood is consequent, and, as I shall endeavour to show, dependent upon it. With respect to the question before us, this view will be confirmed by referring to the aggregate of symptoms as given above, with a consideration of the position of a certain branch of the nervous system, the entire of which branch is in a greater or less degree implicated, while the rest remains comparatively undisturbed. It will, of course, be anticipated that I allude to the nerves of organic life.

The most obvious disturbance is in the functions of the stomach and bowels, as manifested in the *profluvia*, and if I were to ask whether, even in the second or collapse stage of the disorder, their powers are exalted or depressed, I should probably be answered that the former condition was obvious. Let it, however, be remembered that the office of these organs is not merely to expel their contents, but that *secretion* is of paramount importance and I think the nature of the matters expelled during life, and their contents after death, are such as would oppose such a conclusion, as certainly as the idea is precluded that in general anasarca—say from debility after scarlatina—the serum of blood is *secreted* by the areolar tissue; instead of which, we shall in both cases find that what in the former supposition must be regarded as agents, are but the passive recipients of their contents.

That the power of secretion is suspended is sufficiently demonstrated by the cessation of action in the kidneys, shown by the total absence of urine, and by the fact that the evacuations are free from bile or fecula. With respect to the former, it might be objected that the fluid is carried off by the bowels. This, however, will not apply to the latter, for bile is found to exist in the gall bladder. Now every one knows that this fluid is not capriciously poured out, but that stimulation of the duodenum is necessary to excite the action of the biliary apparatus. The failure of this is not from emptiness of the duodenum, such not being its state. Still it may be answered that the fluid contained is not chyme, and therefore not stimulant. It cannot, however, be shown that actual chyme is essential to excite this organ, but, on the contrary, we know that bile passed through the intestines when the stomach has provided no such fluid; that, like the stomach, its action in health may be induced by the presence of even inert matter. The argument, too, that deviation in the course of the urine in the absorption of serum by the larger and free canal of the intestines is sufficient to account for its absence in its proper vessels, without attributing to the kidneys, &c., a suspension of power, will not hold, for I have seen the kidneys and ureters filled with the same fluid as that in the intestines in an inspissated state, extending to and lining the bladder, in which, however, there was not one drop of urine; proving their passive condition as mere mechanical passages.

Beside, a further proof is deducible from the complementary evidence of two facts, viz., that those cases in which the cessation of the abnormal evacuations is not quickly followed by those which are normal, are more certainly and rapidly fatal; while, on the other hand, when these do follow,—indicating the change from a passive to an active condition,—recovery may be safely prognosed. And again, we may adduce the enormous quantities of otherwise powerful medicines sometimes administered and remaining inoperative—such as calomel, to the extent of drachms.

It appears, then, that the stomach and chylopoietic viscera, as no longer stimulable, from the almost total cessation of their nervous circulation. I say almost total cessation; for, if the extreme atony were perfect, we should, of course, have an entire freedom from sensation, and all action would be at an end.

The nerves are not, however, in a state of absolute atony, but the circulation of the fluid, in one branch especially, is imperfect, irregular, and consequently spasmodic.

This leads me to consider the sanguineous congestion, so manifest, especially internally, and which would be still more evident, but that the blood is so much diminished in bulk by the drainage of serum.

In cholera, the energy of the heart is somewhat diminished by the partial atony of the nerves ministering directly to it, and a still greater proportional diminution of power in the arteries supported and conducted to the other viscera by the nerves of organic life; the blood is therefore no longer propelled to the surface, but congested in the internal parts, and there drained of its serum; consequently offering a further mechanical obstruction to free circulation,—producing at the former, paleness, shrinking, and cold; and in the latter, fullness, heat, and thirst. Moreover the blood, no longer conducted in sufficient quantity to the lungs, whose action is also itself diminished, is not duly oxydated, and being drained of serum, the black, thick, tar-like appearance of the fluid is produced, and is externally visible at those parts where it is most easily seen through the skin, whether from greater transparency or from the natural arrangement of the vessels at the thin extremities.

In the decreased circulation and oxidation of blood we have diminished stimulation, accounting for the mental apathy the patient frequently evinces; and while it is produced by, tends to prolong the atony of the nerves, operating as both effect and cause in quickly bringing about a total cessation of life.

Maintaining, then, the position, that Asiatic cholera consists in the almost total suspension of the function of secretion in certain organs, with irregular and partial sanguineous circulation, resulting in passive congestion; both dependent on their primary irregular circulation of nervous fluid from partial atony of that branch of the system which sustains organic life;—our attention is directed to those remedies which restore tonicity; and in a disease so fearfully rapid we may with propriety select such as are most rapid and energetic in their operation.

A consideration of the utmost importance obviously is, to begin at the right end; which certainly is not the surface of the body. Our operations must be directed to the citadel, through the portal, the stomach. Its condition, it must be confessed, offers a formidable resistance in the rejection of ingesta, but its efforts are not incessant. We may, therefore, reasonably hope that the frequent application of a corrective will not be entirely without effect; but of this we will treat after we have determined the general course proper to pursue. And here we shall be materially assisted by our knowledge of another analogous disorder, viz., common intermittent fever, where we have asthenia, or nervous atony, as the correlative of hypersthenia, or exalted tonicity, in alternating paroxysms, against which we fortunately possess a specific in quina, the *modus operandi* of which is highly instructive.

If administered while the nerves are in a state of excitation, in the hot stage, it increases their tonicity, till, being overwrought, they throw off their power, and greater general collapse ensues. Continue the remedy during the interval,—*i.e.*, as before, add to their tonicity or power,—and we bring the system up to the natural standard, able to sustain the next (mitigated) shock; and thus cure is gradually, but speedily and surely, effected.

Now, it is precisely this condition of nerve, in general, that we have to remedy in cholera. It is not stimulable, because atonic.

With the stomach, in particular, I would adopt a similar course, applying not a (now inert) stimulant, but an astringent, which, upon the same principle, being applied to the healthy organ, so overbalances its power that vomiting is produced; but which in this case must first raise it to the natural pitch before such an effect can possibly be produced by it. The most eligible, is, perhaps, the sulphate of copper.

Add to these medicines the corroborant property of cold, which, if exhibited internally in the form of large draughts of water, will possess the twofold advantage of diffusing itself, and the other agents more generally and uniformly, and conducting more directly to the *locus morbi*; and I humbly, but confidently, believe that we need no longer dread Asiatic cholera in its second or collapse stage.

In conclusion, I subjoin the formula I would submit, subject, of course, to the necessary modifications:—

℞ Sulph. cup., gr. ss. to gr. ¼; aq. frig., ℥ iv. to ℥ ij. M. ft. haust. cap. cum. haust. seq., in dos. alt. qq. ¼ to ½ hor.

℞ Sulph. quinæ, gr. v. to gr. iij; ac. sulph. dil., q. s., solv.; aq. frig. ℥ iv. to ℥ ij. M. ft. haust., ut supra.

℞ Mur. amm., nit. pot., aa. ʒ ss.; aq. frig., O j. M. Bib. ad lib., vel p. r. n.

HOSPITAL REPORTS.

WESTMINSTER HOSPITAL.

Communicated by Mr. DOWNE.

Ann Membray, aged 32, the wife of a private in the Coldstream Guards, presented herself amongst the out-patients with a tumour of the labium. She stated that, about five years since, she perceived a small tumour in the labium of the right side, the formation of which she was unable to account for, and, as it did not occasion inconvenience, but little importance was attached to its existence, until about two years since, when it rapidly increased. Leeches and different applications were had recourse to, from time to time, without benefit, and, at the period of her application, it had attained the size of a large duck's egg. From the inconvenience it occasioned during intercourse she was desirous of having it removed. A careful examination was made for the purpose of determining its character, and whether it was in any manner connected or complicated with labial hernia. No evidence of the latter affection being apparent, and the tumour presenting a circumscribed, moveable, fluctuating character, Mr. Holt decided upon its removal. The patient, with some difficulty, was placed sufficiently under the influence of chloroform to render her unconscious of pain, but its administration (although stertorious breathing was produced) was attended with considerable convulsive action, which did not subside during the operation. In consequence of the violent struggle of the patient, a small opening was unavoidably made into the sac previous to the extraction of the tumour, when a quantity of *apparently fœcal matter escaped*, which Mr. Holt immediately examined, but as there was an absence of all *fœcal odour*, and the tumour could be isolated from the surrounding structures, proceeded with the operation, and it was quickly removed; three vessels which bled with some violence were ligatured, the parts brought in apposition, and retained by two sutures and sticking-plaister. Upon examining the tumour, which, with the exception of the small opening made, was taken away entire, another cyst of a smaller character was detected imbedded in its coat, and presented fluid of the same character as that which escaped during the operation, and, upon the tumour being slit open, its internal surface corresponded in almost every particular, with the appearance of a portion of small intestine; it was of a brown, corrugated mucous character, apparently secreting matter resembling liquid fæces, but without the slightest inoffensive odour. The incision quickly healed, and the patient was cured without a bad symptom.

SCIRRHUS OF THE LEFT MAMMA.

Sarah Hoffrett, aged 45, a moderately robust and apparently healthy woman, was admitted August 22nd, with a cancerous tumour of the left breast.

Four years since, without any assignable cause, she experienced darting pains in the left breast, and, upon examination, detected a small tumour of a hard unyielding character, situated almost immediately beneath the skin, and above the nipple; but little attention was paid to it until twelve months since, when it began to increase; and she applied to a Medical Practitioner, when lotions and different applications were had recourse to without benefit, and within the last six months the tumour has rapidly increased. The pain is now very severe, more particularly at night; the tumour about the size of a large orange, adherent to the integument, (which is discoloured,) but not to the pectoral muscle; one gland in the axilla is enlarged, but not painful. The generally unsuccessful termination, and the probable return of the disease having been fully explained to her, she was left to decide whether an operation should be had recourse to; and, considering the importance of getting rid of that which would soon become an offensive ulcer, although only probably affording temporary relief, she was anxious the breast should be removed. Mr. Holt made an incision with a clasp bistoury, first along the lower, and the upper edge of the tumour, continuing it over the gland in the axilla, which, with the diseased mass, was entirely removed. Considerable hæmorrhage ensued, and several vessels required ligature. A piece of wetted lint was placed over the wound, and the approximation of the cut surfaces deferred until all oozing had entirely ceased. In the evening the edges were brought together with three interrupted sutures, and strapping and lint dipped in cold water over the dressing. She experienced but little pain after the operation, and upon examining the wound on the third day, three-fourths were found firmly united by the first intention. On the fifth, pus of a healthy character was secreted the remaining portion quickly granulated, and the entire breast was healed in twelve days. Upon examining the tumour, it presented the usual characters of scirrhus, and Mr. Holt remarked, that he should not have proposed any operation had the tumour remained quiescent, and not exhibited a disposition to ulcerate; but the rapidity of its increase, and adherence to the integument, which was already discoloured, induced him to suggest an operation, more for the purpose of relieving the patient from that which would have quickly become an offensive, ulcerated mass, than any great hope be entertained of a radical cure, although he had operated on two cases of a similar character five years since, and had frequent opportunities of seeing the patient up to the present time, during which period there had not been any return of the disease. He, in a great measure, attributed the success of those operations to the whole mammary gland having been removed, although only a small portion was apparently implicated.

STRANGULATED FEMORAL HERNIA.

Ann Smith, aged 60, a rather emaciated person, was admitted December 23, at half past nine, p.m., with strangulated femoral hernia. She has been the subject of hernia many years, and, except upon the present occasion, has always been enabled to return the greater portion of the protruded intestine with facility. Two days previous to admission, a greater quantity than usual was protruded, which she was unable to return soon became filled with fæculent matter, and upon her admission communicated a labulated and hard ened sensation to the touch. During the greater part of yesterday she had severe vomiting, and now complains of great pain across the abdomen, tenderness of protruded viscus, inclination to vomit, frequent eructations of fœtid gas, countenance anxious extremities cold, pulse feeble and quick, and tongue white. A small quantity of wine was given, and an injection administered, which brought away some hard scibalous matter. She was placed in a warm bath, and efforts at reduction attempted, however without success.

11½.—The pain and tenderness of tumour increasing, and some stercoraceous vomiting having taken place, it was decided the operation be immediately performed.

An incision was made by Mr. Holt over the tumour in a direct line with its long axis, and the different tissues divided down to the sac, which was very carefully opened by a small incision; there was not any escape of fluid, some difficulty being experienced in introducing the director between the sac and the intestine, from the firm agglutination which had taken place, the result of the effusion of coagulable lymph; this was, however, broken down, and the stricture, which was exceedingly tense, and situated at the femoral ring, divided; the intestine was much discoloured, but not gangrenous; it was returned, and the integument brought together with adhesive strapping, a roller being lightly applied over the whole. The patient expressed herself immediately relieved, and Mr. Holt desired she might have a little wine and water, and be left quiet.

24th, 8 a.m.—She has passed a quiet night. The bowels have acted three times freely; a great quantity of flatus passed per anum; no further eructations; skin moist; countenance cheerful; pulse 84, and soft; an absence of all pain; tongue rather white, but moist; and she expresses herself quite comfortable.

10 p.m.—Not having had any sleep during the day, she was ordered 25 minims of Batley's solution of opium, if necessary.

25th.—Progressing favourably; to have beef tea and arrowroot; bowels twice relieved.

26th.—Passed a quiet night, but was attacked this morning with shivering; bowels not again relieved; skin hot, and tongue rather dry; upon examining the wound an erysipelatous blush was detected; fomentations were ordered, and a mixture, with liq. ammon. acet. and excess of ammonia, every four hours; the pulse being feeble, a small quantity of wine was to be administered.

8 p.m.—The bowels have been once relieved; pulse more feeble, and slightly intermitting; skin perspiring; tongue white and dry; to omit the former mixture and wine; and take an ounce of the mist. spt. vin. gallici every three hours.

27th.—Passed a restless night; tongue getting brown and dry; bowels three times open; pulse 84, and feeble.

8 a.m.—Erysipelas slightly extended, and the edges of the wound have a sloughy appearance; continue the mixture every three hours; bread poultice and fomentation to the wound; and take beef tea as often as she can.

3 p.m.—More exhausted than in the morning; bowels again open, and vomiting of a bilious character has supervened. Cap. morph. acet. gr. ¼, creasote ♏j., hyd. chlorid. gr. ii. statim, and repeat every three hours until the sickness is abated. Continue the mist. spt. vin gallici, and wine and water.

8 p.m.—Has had two hours' sleep, and is much relieved.

28th, 9 a.m.—Passed a moderately quiet night; bowels once relieved; pulse 80, and soft; tongue more moist; skin cool; erysipelas somewhat subsided; there has not been any vomiting since taking the pill. Continue the medicine and nourishment, and omit the pill.

9 p.m.—Is somewhat better; no further vomiting, and pulse stronger than in the morning.

29th, 9 a.m.—Passed a quiet night; tongue moist and clean; pulse 81; skin cool; erysipelas on the decline; bowels been twice relieved; abdomen soft, and she can bear pressure at any part without inconvenience. Continue.

7 p.m.—Diarrhœa of a severe character has supervened; she has been four times purged, and is much depressed; pulse feeble, and belly tympanitic; to have a draught of aromatic confection, tincture of catechu in chalk mixture every two hours until the purging ceases; brandy and beef-tea every hour.

30th, 9 a.m.—Passed a restless night; extremities cold; bowels been twice purged. Continue brandy, &c. She, however, never rallied, and died at 1 p.m.

Post mortem.—Upon examining the abdomen, the peritoneum was found in its normal condition; the intestines moderately distended with flatus, but not displaced; the strangulated portion had nearly recovered itself, and was restored to its natural position in the abdomen; the gut in the immediate vicinity, both above and below, was perfectly healthy. Upon examining the mucous membrane of the colon, it presented in its whole course a blackened appearance, spots of blood being interspersed at different points, the whole highly congested, and having a similar aspect to the mucous membrane of patients who have died of cholera. The other organs were healthy.

THE PRACTICE OF THE BELFAST GENERAL HOSPITAL.

(Continued from Page 621, Vol. XIX.)

MEDICAL REPORT.

III.—Asiatic Cholera.

Alexander Gardner, aged 30; labourer; stout; ill 15 hours; died.

Case.—Collapse case; commenced with diarrhœa; and soon after vomiting and cramps collapsed in 6 hours; stools of gruel character; pinkish; duration 24 hours.

Treatment.—Hot-air bath; turpentine and ammonia frictions; diffusible stimuli; calomel and opium after Dr. Ayre.

2. Mary Crory, aged 41; married; ill 64 hours; recovered.

Case.—Admitted with pulse 96, and little depression; vomiting copiously; commenced with diarrhœa; vomiting in 33 hours; evacuations gruel-like; delirium, and contracted pupils in 70 hours; traces of bile in stools in 107 hours, simultaneously with mercurial action; irritable stomach and bowels for several days.

Treatment.—Stimulating frictions; turpentine enemata; soda effervescence; calomel and opium to salivation, commencing at 10 grains; opium for the bilious diarrhœa; and nourishing diet.

3. William Wheaton, aged 43; tailor; ill 88 hours; died.

Case.—Commenced with copious diarrhœa; vomiting and cramps, with lividity, in 78 hours; admitted in collapse; evacuations gruel-like; hiccup on the fifth day; mercurial action on the 6th day; slate-coloured stools on the seventh day; ditto on the ninth; suppression of urine, followed by delirium, on the twelfth day; after a convulsive fit, died on the thirteenth day.

Treatment.—External stimulants; calomel and opium in scruple doses; chloroform and camphor; draughts of castor oil and turpentine; turpentine mixture with sweet spirits of nitre; cupping over the loins.

4. Mary Ramsey, aged 22; ill 3 weeks; recovered.

Case.—Commenced with slight diarrhœa, which became worse on the 24th day; and accompanied with vomiting on the 25th; evacuations like tea; became bilious on the 26th; gums mercurialized on 28th.

Treatment.—External stimulants; calomel and opium; scruple doses; soda effervescents, with laudanum; opium alone during convalescence.

5. Ellen M'Quicken, aged 14; ill 33 hours; recovered.

Case.—Commenced with slight diarrhœa; in 24 hours vomiting and cramps in less; admitted cold and livid; tongue cold, and pulse 120, exceedingly feeble; slate-coloured evacuations on 3rd day; bilious on 4th, after which rapidly convalesced.

Treatment.—Hot bath (at 110°) on admission; stimulant frictions; two ℈ doses of calomel, effervescent draughts, with tr. op.; on 3rd day v.s. to 6 oz.; was not mercurialised.

6. James Nesbitt, aged 36; labourer; ill 15 hours; died.

Case.—Commenced immediately after supper with diarrhœa and cramps; admitted in perfect collapse; dejections rice-coloured, watery; evacuations became dark, with mercurial action on gums on 4th day; bilious stools on 5th; hiccup and slight jaundice on 7th; much salivation; ochry-looking evacuation on 10th; delirious, with convulsions of face on 11th; died on the 12th. The urine had been regularly secreted, but scanty.

Treatment.—Hot punch and stimulant frictions; calomel and opium to salivation, (first dose ℈j., afterwards grs. x. to iv.); Stevens' saline draught; chloroform with camphor was used with effect to allay the hiccup; Sir James Murray's bisulph. alum. et ferri for the bilious diarrhœa; dec. sarsæ c. hydr. potass (2 grs. every 2nd hour, after the mercurial action.

7. Alexander Reid, aged 40; labourer; ill 21 hours; recovered.

Case.—Commenced with painless diarrhœa; vomitings and cramps set in three hours before admission; admitted in perfect collapse; in 24 hours motions became feculent and soon bilious, with mercurial action; discharged well in a few days.

Treatment.—Hot punch, with creasote; stimulant frictions; calomel ℈j. to 5 grs. with opium, to affect gums; saline draught.

8. Ann Boyle, aged 42; ill 4 hours; died.

Case.—Took ill with diarrhœa; vomiting followed in three hours; evacuations rice-coloured; admitted with vomiting, purging, and cramps in limbs, and very weak pulse; evacuations dark on 2nd day; on 5th bilious vomiting, and drowsiness set in with flushed face; on 6th increased drowsiness, with hot throbbing scalp; on 7th stupor and stertorous breathing, with pulse at 80, and face affected with bright erythema; on 8th comatose, and left mamma became suddenly swollen and livid; died early on 9th; urine suppressed last two days.

Treatment.—Usual stimuli; opium and lead: 10 grs. calomel 3 times; turpentine and assafœtida enemata; oil, ether and turpentine draughts; chloroform and camphor; ves. pro nuchæ; effervescents; leeches to the temples, and mercurial dressings for the blistered surfaces.

9. Jane Hervey, aged 30; married; pregnant 8 months; ill 14 hours; died.

Case.—Took ill suddenly with vomiting, diarrhœa, and cramps in legs and abdomen; admitted collapsed, but pulse still with difficulty perceptible; evacuations rice-coloured; cramps in chest; stools became bilious on third day; on this day labour commenced, and after one severe pain, a dead and livid fœtus with placenta was expelled; four hours after began to sink, and died on fourth day.

Treatment.—Usual external and internal stimuli. Opium, capsicum, and calomel (gr. x.), several doses, and saline drink. Assaf. and opiate enema. Stimulants at close: no mercurial action.

10. John Douglas, aged 10; emaciated; ill 14 hours. Recovered.

Case.—Has been occasionally ill for some time past of vomiting and diarrhœa; got over with cramps 14 hours before admission; admitted in collapse, the pulse at times only barely perceptible. Evacuations dark on third day. Soon recovered, but during convalescence attacked with bronchitis.

Treatment.—Hot bath; hot punch; external stimuli. Calomel (gr. x.), several doses; chloroform and ether; wine c. oil and turpentine draughts; blister to chest, and expectorants at close; no mercurial action.

11. Eliza Taggart, aged 41; ill 12 hours; recovered.

Case.—Commenced with diarrhœa, soon followed by vomiting: admitted livid and cold, nearly pulseless, cramps, and precordial oppression; evacuations feculent on following day, with mercurial action on gums; some drowsiness; salivated: soon recovered.

Treatment.—Calomel (℈i. to gr. v.), several doses; effervescents; stimulants, externally and internally.

12. Bessy Watson, aged 27; ill 7 days; recovered.

Case.—Commenced with diarrhœa, which was accompanied first only, on morning of admission, by vomiting and cramps; admitted cold, blue, and with exceedingly weak quick pulse, thirst, and cramps; evacuations gruelly; became bilious third day after admission. Soon quite recovered: mercurial action.

Treatment.—Opium at first; calomel (℈i. to 10 grs.) three doses; external and internal stimuli.

13. Patrick Hughes, aged 24; dock porter; ill 10 hours; died.

Case.—Had been drinking, and (says) he caught cold; commenced with purging, vomiting, and cramps; admitted cold, blue, sunken eye, and very weak pulse at 96; evacuations characteristic, rice coloured; became bilious on third day, attended with hiccup; delirious with laboured respiration on fifth day; suppression of urine complete; evacuations black on sixth day, when he died.

Treatment.—Calomel (℈ i. with opium (gr. ii.); cal. subsequently alone and smaller doses; chloroform and camphor, v.s. to vi. oz. on fourth day; c. oil and turpentine draughts; blister to nape.

14. Patrick Mallaghan, aged 40; ill 4 hours; died.

Case.—Had been drinking hard of late; took ill suddenly with diarrhœa; rice-water evacuations; admitted in perfect collapse, with cramps; evacuations became pinkish on 2nd day, when he died.

Treatment.—Calomel ʒss., with 4 grs. of opium; afterwards three doses, several times; external and internal stimulants.

15. Ann Murphy, aged 40; married; ill 2 days; died.

Case.—Commenced with diarrhœa; which, on third day, was followed by vomiting and cramps; admitted in perfect collapse; evacuations on 4th, light slate-coloured; on 5th, dark slate-coloured; on 6th, decidedly bilious; some bilious diarrhœa succeeded; on 10th, bloody urine; much salivation; stupor on 11th; sank after this, and died on 13th day; urine nearly suppressed from 5th day.

Treatment.—Calomel (℈i.), and opium (gr. iv.) repeated with diminished doses; external and internal stimuli; cupping over loins to 4 oz.; Spt. eth. nit.; turpentine stupes to loins; c. oil and turpentine draughts; opium and opiate enemata for bilious diarrhœa.

In the above list, none but true and well-marked cases of this alarming epidemic will be found; and these in the different forms and varieties met with at the general hospital.

Our experience of the principal remedies used may be briefly given as follows:—

1. *External applications.*—Among these, artificial heat by means of the hot bath, the hot-air bath, bags of heated salt or bran, jars of hot water, &c., were found of essential service in restoring the temperature and rallying the depressed circulation. The bath was used as high as 110°, and was especially beneficial in young persons. Its action was enhanced by adding salt. The hot-air bath has been lauded by some, but does not present any material advantage over the other forms of applying heat. Indeed, we have for a long time given it up here, having observed the other and more economical modes quite as useful. But in applying heat successfully, assiduous frictions are necessary. We generally found the temperature and powers soon revive under their joint application; and this is always the first step to be taken when a cholera case arrives at the Hospital. To rouse the nervous and circulating systems still more effectually, the frictions must be performed with turpentine, or ammonia, or camphor liniments; and their action assisted by sinapisms to the extremities and the epigastric region. This to be never omitted, if cramps be present, and these external appliances persisted in until some decided revival takes place. Generally, from ten to thirty minutes' time suffices to bring about this favourable change.

2. *Stimulants.*—When the patient is brought in in a state of collapse, or a condition bordering thereon, the natural indication is for the diffusible stimuli-spirits, either whiskey or brandy, with ammonia and ether, are given with advantage, and aid the external remedies in restoring the temperature and oppressed circulation. Afterwards they may be given in very moderate quantities. But, while approving of this limited use, we must at the same time assert their inutility, or even positive injurious tendency, in immoderate doses. Useless, if the timely use is unsuccessful—injurious if re-action set in, by making it more serious. We advocate, then, only the moderate use of stimulants, only freely given when collapse is impending.

3. *Opium.*—In all cases this drug was administered, in some very largely. It seemed to act most beneficially in the early stages—indeed, its efficacy bore a direct proportion to the period of the disease, the earlier the more useful. We do not remember having seen its narcotic effects induced in true cholera, though it was given frequently in ordinarily poisonous doses. In cholera cases, verging upon or in collapse, the pupil is usually contracted, and, at first, this circumstance was deemed by many as the effect of the opiate treatment; but it was soon found to exist in cases where no such effect could have been anticipated from the quantity employed. In using this remedy, it was found that persistence in its use, after a few good doses, was ineffectual, and it was our custom to stop its administration whenever 5 or 6 grains (given in divided doses) proved useless. When diarrhœa and cramps co-existed, much more was indicated and given than in other cases; and frequently, when administered early, with a proportion of stimulants, many cases recovered which, there is reason to believe, would have run into collapse.

4. *Calomel.*—There are three modes in use of giving this remedy, viz:—1. Dr. Ayres' plan; small and very frequently repeated doses, with small quantity of laudanum. 2. Dr. Clanny's; a few very large (ʒss) doses: and, 3. Moderately large doses given generally (except at first) without opium, and continued at irregular intervals,—intervals varying according to the varying symptoms of progress. The 1st we tried in three bad cases with fatal results. The 2nd also without success; and the 3rd is the mode on which we chiefly rely. It is difficult to say how this remedy brings a bad case through; but that it does so not unfrequently we are confident. Sometimes it salivates, and this action and the beneficial change seem to be synchronous. But, again, in many cases of recovery, no such effect on

gums or system ensued. Here its beneficial operation was indicated by the return of the bile. Its action seems sedative. We have seen the most violent vomiting and purging, (characteristic,) checked at once by two or three 9 doses without laudanum. In using this drug there is little fear of bad consequences on the gums or mouth, however freely it may have been administered.

5. *Bleeding.*—We have practised this only in stage of re-action, and have both generally and locally. Its use is indicated to remove cerebral and venal congestion, and in the few instances when used it was essentially beneficial. No case presented itself in the early stage, when it seemed at all likely to be useful; and in collapse, the extreme torpor of the circulation, and the poisoned stagnation of the entire fluid, presented little hope of any benefit.

6. *Enemata.*—This form we employed in administering turpentine, opium, starch, nitrate of silver, and creasote. Upon none of these cases can we rely in the confirmed and advanced stages. The injections were either returned or were of no effect. The opiate enemata, in the very first stages, did seem of use, but not more so than the administration of the remedy in the ordinary way.

7. *Salines.*—Dr. Stevens' mixture was employed in many cases, but more as an adjunct than a primary treatment. We cannot state anything positive regarding it. Its use certainly did not lead us to employ it with much hope of success. It demands, however, further trial. Soda, effervescent draughts, we gave largely and with benefit, checking vomiting, and allaying the urgent thirst better than any other remedy besides; they did not in any degree aggravate the diarrhœa.

8. *Astringents.*—Of this class, acetate of lead, preparations containing tannin, Sir James Murray's bisulphate of alum, and iron, and turpentine, were severally employed. In all the forms of diarrhœa, save the confirmed choleric, their use we found frequently beneficial; but even here uncertain and temporary, unless aided by opiates. We certainly observed nothing specific in any of them.

9. *Diuretics.*—Though the bilious secretion has been restored, we may be a long way off recovery, on account of the obstinate suppression of urine. In most cases of fatal re-action, this state, by accumulating the poisonous urea in the blood, carries off the patient. Diuretics, therefore, seem indicated. We find, however, the so-called class very imperfectly useful. Squill, sweet spirits of nitre, juniper, iodide of potassium, and turpentine seemed of little avail. Cupping, leeching, or stimulating the lumbar region, we observed of much more direct benefit, sometimes the urine appearing within an hour after such treatment; and the pathology of the disease at this stage evidently leads to this view.

Besides the above, we may mention, that in cases of great irritability of the stomach, we found creasote of some use, and in some cases of hiccough with cramps, chloroform with camphor we employed with evident benefit. Electricity (from the magneto-electric machine) we have applied, but were not induced to repeat it often. Camphor invariably formed a part of our stimuli.

The diet we principally enjoined was chicken-soup, toast-water, arrow-root, eggs beaten up with spirits, during the disease; and rice, veal, mutton, or chicken-soups and bread during convalescence. The usual potations were the saline drink, or cold water, or toast-water, or soda effervescents with or without stimulants.

The above is a brief but correct general view of the mode of practice in managing this formidable disease in the Belfast General Hospital. We have, it will be seen, not omitted to employ remedies of repute elsewhere; and though we cannot boast any specific or even any single efficient remedy, yet we believe our general line of treatment is as steady, rational, and as effective as any of which we possess authentic records.

[To be continued.]*

* The next series will comprise a list of cerebral cases.

PROGRESS OF MEDICAL SCIENCE.

FRANCE.

[From our own Correspondent.]

Ecce iterum Crispinus,—that is to say, the cholera, which continues to creep on in a manner that begins to excite some apprehension. On Wednesday, for example, the mortality from cholera, in the hospitals, was 31; and in the city, 28; making a total of 59. Since then we have had an increase of one or two per day. Still the total mortality does not exceed the average of ordinary times, which ranges from 60 to 65 a day.

The Academy of Medicine has recently received from the Prefect of Police an official account of the mortality, for the first six months of 1849. It runs thus:—

Mortality from various diseases.		Cholera. In city.	Cholera. In Hospitals.	Total of cholera.	General total
January	2755	—	—	—	2755
February	2545	—	—	—	2545
March	3156	130	440	570	3726
April	3270	694	1176	1870	5140
May	3115	2426	2098	4524	7639
June	3886	5769	2214	8713	11599
	18727	9019	6658	15677	34404

From the above it appears, that of 34,404 deaths, which occurred during the first moiety of the present year, at Paris, 15,677, or nearly one-half, occurred from cholera; and if to these we add 790 deaths in July, and as many in August, we arrive at a sum total of 17,257, little different from that of 1832, which reached 18,556. There is, however, this remarkable difference between the two epidemics, viz., that nearly three-quarters of the deaths, in 1832, or 12,471 out of 18,556, occurred in a single month,—the fatal month of March.

The sweating sickness appears to have taken its departure from the capital, without having excited much notice. The cases, indeed, were mostly of an insignificant kind, showing rather the effects of an epidemic constitution, than an actual malady.

I regret to state, that the chief symptoms under which General Cavaignac has laboured for so many years, have assumed a character which renders it necessary for him to change climate.

Andral, it is said, has been summoned to London, to hold a consultation with our "Summites," on M. de Metternich.

THE NATIONAL EXHIBITION.

Medicine and her accessories have not been forgotten in the immense collection of national products which forms the exhibition in the Champs Elysées. The Chemists hold the first rank. No less than sixty-seven manufacturing houses or companies have enriched the collection with a variety of rare and useful products, to which I propose to call attention in my next.

The Pharmaceutical products have been furnished from ten houses, not forgetting the interesting specimens sent from the Government establishment at Algiers.

For surgery, we have the instruments of Charriere —*facile princeps*: of Luer, a German maker in the Place de l'Ecole; Portier and Co., successors to Sir Henry, as he was called, probably because a Knight of the Legion of Honour; of Bordeaux, from Montpellier, and several others. I do not find anything from the hand of old Carter, who has represented English cutlery for so many years in the Place de l'Odeon.

The dentists, of course, cut a magnificent figure —at their head the Dean of quacks, Desirabode; but these we may "leave alone in their glory." Of inodorous apparatus, and instruments of every kind to overcome refractory bowels, there are abundance. To see the long line of the latter, one would imagine that the French were the most *costive* nation on the face of the earth. Yet we have daily, and alas! ocular proof of the contrary.

An artist might fill a rich album with these curious devices; but, as I have no taste in this line, I shall rather direct your attention to

ARTIFICIAL ANATOMY AND PATHOLOGY. DR. AUZOUX AND MADAME THIBERT.

The productions of Dr. Auzoux form one of the most interesting divisions of the National Exhibition; of their unrivalled excellence and utility it is unnecessary for me to speak; but it is not, perhaps, so generally known, that Dr. Auzoux has converted his art into an industry, and established a regular manufactory at his native place, St. Aubin, in which from sixty to eighty workmen find profitable employment all the year round.

As there is "nothing new under the sun," so we learn that we are indebted to the Greeks for the original idea of imitative anatomy. Pausanius informs us, that the Grecian statuaries made anatomical figures in marble and bronze; and there still exists, in the Museum of the Vatican, a fragment of one of these statues, representing the osseous framework of the human chest. Marble soon gave way to plaster, and the latter material to wax. Colouring was now added to the famous productions of the Florentine School, (of which Trinity College, Dublin, possessed a fine collection,) leaving little to be desired, either for faithfulness of representation or beauty of work. It would, however, appear that the honour of having first applied colour to the wax models belongs to a Frenchman, Maitre Jacques, of Angoulême. Up to the middle of the sixteenth century, Rome still possessed three admirable anatomical figures of this artist, from which, it is said, the immortal Michael Angelo derived his knowledge of the anatomy of the human frame. Maitre Jacques transferred the art to Italy. Zambo, of Syracuse, made several remarkable preparations during the reign of Louis XIV.; amongst others, a head, which exists at the present moment, and displays the anatomy of the brain, eye, and ear.

In 1750, Galli, of Florence, illustrated the history of pregnancy; Lelli and Mantolini reproduced the generative organs of both sexes, and finally, MM. Bertrand and Dupont, of Paris, made their celebrated collections, illustrative of the infinite evils of the venereal disease.

The labours of Dr. Auzoux commenced about the year 1820, and since then his life has been devoted to the cultivation of his art. The material which he employs is one of his own composition, differing considerably from the paste known under the name of "carton-pierre," or stone pasteboard. It is easily cast into moulds, dries speedily, becomes elastic, and acquires a solidity almost equal to that of wood.

I need hardly mention, that the grand object of M. Auzoux's preparations, is to facilitate popular instruction in anatomy; and for the "vulgus" the preparations are just as useful as the originals could be. Several specimens, in the present exhibition, contain a complete cabinet of human anatomy in a single model, the prices varying from 10*l.* to 120*l.* sterling for each. But M. Auzoux does not confine himself to human anatomy. This year he gives us an admirable series of specimens intended to illustrate, on a grand scale, the comparative structure of the different classes of animals. Thus, the mammalia are represented by a horse; the class of fishes, by a skate; insects, by a hanneton, and by the silk-worm; the mollusca, by a snail; the annelydes, by a leech; and the zoophytes, by a polypus.

The model of the horse, which is three feet two inches high, can be taken to pieces on the left side, and as each piece is removed, the original anatomy of each part is successively displayed in the most admirable manner. But the *chef d'œuvre* of the collection is the silk-worm, a gigantic model two feet in length, in which the minute structure of the insect, and its silk-making machinery, are wonderfully brought to light. What Auzoux has done for normal anatomy, Dr. Thibert undertook to execute for pathology. Rejecting wax preparations as of too perishable a nature, he invented a species of model in relief, coloured after nature, and resembling the original with the most scrupulous exactness in every respect save that of texture. Thibert was removed from the sphere of his labours by a premature death; and Dr. Bourgery, who undertook to complete the collections of the Rue Hautfeuille, fell a victim to cholera; but Madame Thibert survives, and the preparations which she has sent to the

Exhibition this year are calculated to give a very high idea of their value. It is, in fact, impossible to imitate every shade and form of pathological production in a more complete manner; and I cannot avoid here expressing a hope that so much talent may not be left without due encouragement. Several of the rarer specimens ought to find a place in every museum throughout Europe.

MECHANICAL LEECHES.

Amongst the medical curiosities of the Exhibition, I must not forget the mechanical leeches of M. Alexandre. Though not endowed with locomotion, they have probably found their way into England before this; my notice shall, therefore, be brief. The main qualities of the new annellidæ are two—they bite always and never die. In short, they are nothing more nor less than two little tubes, a suck ing and a scarifying one—the former in glass, the latter in copper—destined to imitate the two acts of the leech. It would, however, be more correct to denominate them "tubular cupping-glasses," for such they are in reality. The value of the modification experience alone can determine; but I doubt much that they are destined to supersede leeches altogether. I have not seen them employed myself; the Academy of Medicine, however, reports favourably of them, and says, "the instrument is a very useful one, and may replace leeches with advantage in the great majority of cases." The Ministers of War and Marine, and the Directors of the different Hospitals, both Civil and Military, have ordered these leeches to be employed in the different establishments under their control. M. Alexandre has made an excellent "hit," if nothing else.

THE INTERMITTING SYPHON.

One of the most ingenious instruments in the Exhibition is the intermittent syphon of M. Bloch, Assistant-Chemist at the School of Strasbourg. It is of a somewhat conical form, the smaller end being placed in the fluid to be filtered. The fluid passes very gradually from the smaller to the larger branch of the syphon, and it accumulates in the latter until its weight overcomes the tubular attraction, when the little column falls into the filter. This occurs four or five times a minute, and the quantity discharged by the instrument exhibited appears to be about a scruple, or something less. It is unnecessary to point out the utility of this simple instrument in chemical and pharmaceutical operations. It also gives us the means of solving a very difficult problem in hydraulics, viz., that of keeping a constant level in a vessel which discharges its contained fluid; for we all know that the velocity, and therefore the quantity, of the fluid discharged diminishes as the square root of the "head," or elevation of the fluid above the orifice. The principle might—it strikes me—be applied to lamps and the boilers of steam engines; but this concerns Dr. Ure rather than the *Times*. If it has not yet found its way to England, the syphon may be procured at the Rue des Fossés Montmartre, No. 17.

SCOTLAND.

[From our Edinburgh Correspondent.]

Edinburgh is, as usual at this season, excessively barren of interest. One of the few topics that keep discourse alive is the vacant St. Andrew's chair. There is no lack of candidates, and Edinburgh is at present their head quarters. Among those who have already announced themselves are—Dr. George Paterson, Dr. George E. Day, Dr. P. Redfern, Dr. R. M. Glover, Dr. A. G. Melville; and to these we believe we may add Mr. John Adamson, of St. Andrews. They are all good men. Dr. Paterson is well known in Edinburgh, being Secretary to the College of Physicians, and an Infirmary Physician of eight years' standing, a popular lecturer on Clinical Medicine in the extra-academical school, and formerly assistant-lecturer in the University Clinical Course. Dr. Day is a Fellow of the London College of Physicians, the well-known translator of Simon and Vogel, and the author of a late work on the Diseases of Old Age. He distinguished himself when still a student here, by a very able essay on the Chemistry of the Urine, which gained the Harveian prize. Dr. Redfern is Lecturer on Anatomy in King's College, Aberdeen. He was a distinguished Edinburgh student, and afterwards obtained high honours at University College. Dr. Glover is one of the Newcastle lecturers. Like Dr. Day, he gained the Harveian prize when a student here, his essay being on Bromine. He has since become known to the Profession for his able treatise on Scrofula. Dr. Melville is the recently appointed Professor of Natural History in Queen's College, Galway. He was formerly Demonstrator of Anatomy in our University, and is the author of several memoirs—among others, of a late interesting work, on "The Dodo and its Kindred." Mr. Adamson is a highly ingenious person, well known as a Medical practitioner in St. Andrews, of whose services the University has availed itself latterly in the conduct of the course of Chemistry. It seems to be pretty certain now, that no attempt will be made, as was at one time expected, to convert the Professorship of Medicine into a chair of Natural History. The party in the University favourable to that change are, we understand, a decided minority, and have turned their expectations of providing a lectureship of Natural History into another channel.

We observe, by the report of the proceedings of the National Institute, in last Saturday's *Medical Times*, that we here are not singular in ascribing the delay of the Medical Reform Bill to the obstacles raised by the Council of the London College of Surgeons. It is really too bad, that so small a body as the Council should be permitted to thwart the general wishes of the Medical Profession. But we trust the obstructive few will not be able to domineer much longer. New men are getting into the Council, and the balance must, ere long, turn in favour of more liberal sentiments. The electors should be called on to muster in force, and supply the two vacancies caused by the retirement of Mr. Welbank and the death of Mr. Goldwyer Andrews, with men who will carry with them into the Council some sympathy with the general sentiments of the Profession.

We see Mr. Henry Smith, in your pages of last Saturday, singing a pæan over Mr. Syme, on the old story of the excision of the head of the thigh-bone. Mr. Smith still forgets, that the question between them is not, whether the head of the thigh-bone can in any case be removed with a successful result; but whether there be any instances of disease, coming strictly under the head of morbus coxarius, in which such an operation is expedient. Mr. Syme says, that in that disease this operation will have a favourable issue in those cases only in which recovery would have spontaneously taken place. Mr. Smith contents himself with assuring us that the girl in question has completely recovered. He asks us to believe, without satisfactory evidence, that the case was one of unequivocal morbus coxarius. The disease had its origin in a pretty severe injury. Mr. Fergusson admits, that the disease might have recovered spontaneously, and tells us himself, that, before the operation, he removed a portion of loose *necrosed* bone; and Mr. Smith is particular as to the acetabulum being filled up with a deposit of new bone. Is it unreasonable, then, in us, to ask for distinct evidence of this having been an example of genuine morbus coxarius? Is it so certain, from the meagre account given of it, that it was not rather allied to the still little-studied cases of necrosis affecting the articular ends of bones? Without stopping to inquire what Mr. Syme thinks or has said of this particular case, there is no difficulty in admitting, that Mr. Fergusson was right to operate, as the result shows. But, while the expediency of the operation is allowed, in a case plainly partaking more of the nature of necrosis than of caries, no inference is warranted in favour of the operation in unequivocal examples of morbus coxarius. What would Mr. Smith say to an argument of this kind:—A says he has cured twenty cases of cancerous mamma by operation. B replies that cancerous mamma is not curable by operation. A triumphantly brings evidence that he has removed the mamma twenty times, and shows to everybody's satisfaction that the women notwithstanding are all alive and well. What follows? Not that A is right, but that he has yet to learn the nature of a *non sequitur*.

We have had some straggling cases of cholera here of late, but we are very unwilling to believe that they are numerous enough to amount to a distinct revisitation of the epidemic. Indeed, both on this occasion, and on the last in 1832, the disease has assumed less of an epidemic character in Edinburgh than in many other towns. In 1832 it began in February, and went on attacking but few for many weeks; in May it became more prevalent; sunk again; rose again in July; and, after sinking a second time for a week or two, began to rise again towards the end of August, and continued increasing throughout September and great part of October, in which last month it reached its maximum; it then gradually sunk in November, and finally disappeared in December. In most seasons the ordinary bowel complaints of this country are probably most frequent with us in September and October, and from the course just indicated in 1832, we can hardly flatter ourselves that the disease will altogether cease here till the usual season of bowel complaints has passed by. Our statistics of cholera were more exact in 1832 than they can be at present, owing to the want of power in our authorities to compel practitioners to report their cases. We feel the want of the Cholera Act which was in force at the last visitation, by which a penalty was imposed for neglect to report.

AMERICA.

PROXIMATE AND ULTIMATE ELEMENTS OF FUNGI.

Dr. J. K. Mitchell, of Philadelphia, says, of all vegetable substances the fungi are the most highly animalised. Like animals, they disengage carbonic acid and imbibe a quantity of oxygen; nay, some of them extricate hydrogen, and even nitrogen. Their chemical composition also allies them to animal structures. They yield the vegetable products, resin, sugar, gum, fungic acid, and a number of saline compounds; but they also afford the adipocere, albumen, and osmazome of the animal kingdom. The basis of these plants is fungin, a tasteless but highly nutritious substance, white, soft, and doughy. It yields by nitric acid, nitrogen, hydrocyanic, oxalic, and some other acids, and fatty substances, like wax, tallow, and, in some instances, oil.

ASSOCIATION OF FUNGUS LIFE WITH THE EXISTENCE AND PROPAGATION OF GREAT EPIDEMICS AND INTENSE ENDEMICS.

Dr. J. K. Mitchell quotes a number of writers who have recorded the presence of "moulds," of a white, yellow, grey, or even black colour, adherent to the roofs of houses, pavement of cities, to articles of wearing apparel, and domestic utensils of wood; also of "blood rain," a red blue earth brought down with showers, and the rapid decay of fruit, at the same time, with plagues, pestilence, and violent fevers. In Africa, when the rains and the sickness commence together, the fungiferous powers are fearfully developed. According to Park and Lind, the first rains stain the clothes, and make even woollens and leather mouldy and rotten in a day or two. The like extraordinary tendency to the production of moulds has been noticed in different parts of the United States, during the period of epidemics of yellow fever, and also in cholera. So, likewise, was it in the *sudor anglicanus*, and in the epizootics of cattle.

TREATMENT OF HYDROCELE.

Dr. Horner, of Philadelphia, in his communication to the Committee of the American Medical Association, remarks, that he has found the treatment of hydrocele rendered much more certain by the introduction of a few threads passed through the tunica vaginalis from the bottom to the top, even where the process by injection is the main feature of the case. His experience has shown him that no injection is to be wholly relied on, unless in connexion with subsequent treatment. The effect of any irritating injection into the tunica vaginalis, he observes, is not only to produce a secretion of

lymph, but also of serum, and if the latter accumulates, it will of course keep separated the opposed sides of the tunica vaginalis; hence a common cause, perhaps the most frequent, of failure in all injections. This obstacle, he adds, may be very easily overcome with four or five threads of silk, which will carry off the serum as fast as it is secreted, and thus allow the two surfaces of plastic membrane to touch and coalesce.

IODINE IN THE TREATMENT OF SNAKE-BITES.

Dr. Whitmire states (*North-Western Med. and Surg. Journ.*) that he has used the tincture of iodine in cases of the bites of the rattlesnake, viper, and copper-head, in both man and beast, with the effect of putting an entire stop to the swelling and pain of the bitten part in from 12 to 16 hours. He paints the bitten part over the whole swelling with three or four coats of the tincture twice daily, and should the swelling extend, which it almost always does after the first application, if made soon after the infliction of the wound, he repeats the application. The third application puts a stop to the extension of the swelling, and three or four more will generally restore the limb to its natural state, except, perhaps, sensibility to the touch, and soreness of the muscles.

TO CORRESPONDENTS.

Our Correspondents must pardon us if we again remind them, that all Communications intended for the Editorial department of this Journal are to be addressed, not to its Publishers, not to Mr. This or Dr. That, but directly to the Editor of the *Medical Times*, 147, Strand.

We have also to request that gentlemen, when they favour us with communications, will have the candour to inform us, if, at the same time, they have forwarded copies for publication to any of our Contemporaries. Every Editor ought to be allowed to exercise his own judgment as to a Communication being of sufficient value or importance to warrant its appearance simultaneously in more than one Journal. For our part, we claim the right to use our editorial discretion as to the admission of such papers into this Journal; and, after the above Notice, the columns of the *Medical Times* will be closed against those who may offend in this matter. Moreover, we would remind whoever it may concern, that the act of sending the same paper to contemporary Journals has a very quackish, and therefore unprofessional appearance; it seems as if the writer sought more to circulate his own name, than to advance science; and, when such a motive influences an author, then, in our opinion, an advertising column of the daily press is the most appropriate medium for his purpose.

TO SUBSCRIBERS.

New Subscribers will oblige by forwarding their Names direct to the Office, 147, Strand, or to the News Agents or Booksellers. All Post office Orders should be made payable to the Publishers, WM. S. ORR AND CO.

THE MEDICAL TIMES.

SATURDAY, AUGUST 25, 1849.

PERHAPS no more lamentable exhibition of the total absence of philosophical principle, as a guide to the attainment of knowledge, was ever displayed than that of the conduct of the Medical world, in testing the efficacy of the various remedies proposed for the cure of cholera. Great were the anticipations, loud the boastings, of what science would effect if that disease invaded Europe. In time it afforded the learned every opportunity for exerting their skill. But, after they had watched its every phase, and analysed with the vaunted crucible and lens the blood and organs of its victims, they saw the disease depart, leaving them as uninformed as to its nature and its cure as when it first came among them. Nay, more; not only had they discovered no specific,—not only had rationalism and blind empiricism failed to supply the one great desideratum—a cure; but they had also failed in that which, had they combated the disease with system, they must have succeeded, *i. e.*, in determining the comparative efficiency of any of the countless remedies proposed. And now that cholera has re-appeared, after an absence of seventeen years, it finds, and bids fair to leave us, in the same doubt, not only as to how it ought to be treated, but how it ought not to be treated. There is not a remedy but has its advocates,—there is not a remedy that has been fairly tested. Doctors differ,—so laymen interfere, and confusion is worse confounded. The most opposite treatments have their advocates, and every advocate proves, at least to his own satisfaction, that his remedy cures, that he knows why it cures, and why it always must cure. We hear men, who acknowledge that they have lost nearly half their cases of collapse, talk of the treatment they found efficacious—the efficacy of a mode of treatment under which 45 per cent. of the patients died! Other men, grave men, honourable men, assure us, that not more than 3 per cent. of their patients die; and anon, other men, grave and honourable men too, confidently affirm, that the cases on which the former founded their statements were not cholera, but trifling ailments from which the patients would have recovered without any treatment. The officers of the only Institutions where the value of the boasted therapeutics could be put to the test, appear driven about by every wind of doctrine—to be "in wandering mazes lost."

In not a single Hospital, so far as we can learn, has a method of treatment been systematically adopted; so that, when the present epidemic ceases, we shall be as wise as we were when it burst upon us; and, if it ever reappear, we shall have the old medicaments again urged on the Profession to hurry—for all cannot be good—more victims to the grave.

The natural history of the disease is unknown. Comparative results are unattainable, because no method has been adopted, no treatment steadily carried out.

This subject has been again thrust on us by a Circular we have received, just issued by the Royal College of Physicians, but dated August 6th, 1849, which runs thus—

RESOLUTION OF THE CHOLERA COMMITTEE.—"That Hospital Physicians and other Members of the College be requested to communicate the results of their experience on the subject of Cholera, as at present prevailing, to the Secretaries of the Committee."

If, before the inroad of the epidemic, the Cholera Committee had examined the evidence in favour of the various methods proposed in 1832—to show how it might have been accomplished we may refer our readers to the excellent papers of Mr. Ross, published in our own Journal—had then issued a brief statement of those plans of treatment, and an abstract of the evidence in their favour, had joined to such a document a proposal that the patients admitted into the hospitals and workhouses should be placed in rotation as they entered, under each of the methods of treatment which, by the evidence adduced, seemed the most trustworthy,—we should now be in a position to estimate the value of these systems; and if we had only *proved*, that the loss of life was greater under any one of the methods proposed than under the others, we should have made one step in advance, at least we should have one less impediment to overcome in our search after truth. But now the results only of the experience of the Fellows and Licentiates—the Cholera Committee ought to have known that there are no Members of the College—are asked. Why, how can any results have been obtained when the treatment has been different for every patient admitted? We strongly suspect, that Drs. Stevens and Ayre would repudiate the mode in which the treatment they respectively advocate has been conjoined with that they utterly condemn—brandy, ginger, cinnamon, calomel, chloroform, opium, and salines have been thrust indiscriminately down the *same* unfortunate's throat, and the patient said to have died, according to the whim of the reporter, while under the treatment recommended by Dr. Stevens or Dr. Ayre.

Blind empiricism, that is, experience unaided by method, and shallow rationalism,—theories unsupported by facts,—have alternately guided the treatment. No system has been adopted, therefore no results can have been obtained. When will the rules of induction guide Medical observers in their search after therapeutic truths?

Since writing the above, the Registrar-General's Weekly Return and the last notification of the Board of Health have reached us. The latter offers but little novelty in the way of treatment; opium is still the panacea, and the objectionable compounds previously prescribed are again recommended. The former has only to give the details of a gloomy picture of the health of the Metropolis, and to lament the absolute inadequacy of the "general sanitary measures now in operation to the emergency," and the want of those simple administrative arrangements by which efficient medical relief might be placed within the reach of the people.

This last evil must become daily greater so long as the epidemic extends, unless the Parochial Boards are willing to engage a larger staff of paid officers for each district, or to afford something like fair remuneration for the services of their present Medical men, so that they may obtain for themselves efficient assistance. For men, like the St. Pancras Board of Guardians on Tuesday last, to bid the poor apply in greater numbers to Medical men, already, according to the Registrar-General's report, taxed "to the utmost of their power, and discharging their painful duties with praiseworthy diligence and humanity," without enabling those men, already miserably paid, to obtain assistance at the cost of the parish, is, indeed, absurd. All are agreed,

that the premonitory Diarrhœa—our remarks at the commencement of this article apply to cases of collapse,—is under the control of medicine, if judiciously prescribed and promptly administered. Then, we assert, that these Boards of Guardians—Guardians of the poor, indeed!—are morally guilty of the death of every individual among those committed to their charge, who may have died for lack of Medical attendance.

THE TEETOTAL QUESTION.

We beg to recall to the attention of our readers a very sensible German article on Teetotalism, by Dr. Metz, a translation of which appeared in our Number of the 11th instant. Most of the practical relations of the subject, both as regards past experience and future conduct, are there definitively stated. It only remains to us to add a few words concerning the position and bearings of the question, as regards the English Medical Profession.

The more indiscreet partisans of the total abstinence views would ensure a very speedy settlement of the question, and upon what they consider very indisputable evidence. They would fain quote instances of the abuse of alcohol from the Old Testament, or praises of temperance from the New; and, with these as their watchwords, dispense judgment and vengeance upon all who cannot receive their dicta or obey their commands.

Fortunately, however, the tide of theological dispute has ebbed from this point of late: its waves have been dashing all too fiercely around Mr. Wortley's Bill, and have left the former controversy high and dry on a quiet sand-bank of indifference. Long may it rest there!

The physiological features of the question are, however, almost as fierce matters of contest: and the most ludicrous statements and counter-statements have been made on both sides. This, we are bound to say, is more a feature of the abstinence party than of their antagonists: the latter are generally, from their profession and position, men of at least average information, who have often deservedly earned the melanotic honours usually obtained by fighting a sweep. The former hardly require that their station and character should be described, for the Brick-lane Branch Association is immortal, and the converted fireman Mr. Anthony Humm, the disinterested vessel Mr. Jonas Mudge, and the gifted hero of the wooden leg, all are, or ought to be, the mental property of every reader.

Once for all, it is clearly recognised, that alcohol is not food; or, in other words, that it undergoes no digestion, but is received at once into the vessels. Whatever be the modifications which it undergoes in the blood, it is highly improbable that they can ever render it like unto the constituents of the body, or, in brief, can ever result in a genuine assimilation.

Still it must be recollected, that, on the one hand, what modification cannot accomplish, decomposition may. On the other hand, to say, that it is not food, is by no means to deny its necessity or usefulness, for the same might be said of air or light. The fact alleged would widely distinguish it from beef and bread, but it would not assert it to be necessary or unnecessary, advisable or inadvisable.

The facts upon which we must predicate these qualities of alcohol are very different. Does alcohol modify life? and, if so, how? What influence does it exert on the organisms of its moderate users, and of its habitual abusers? And what is the effect of its non-use on those who altogether renounce it?

At present, a complete answer can scarcely be returned to all of these questions. The habitual and excessive use of alcohol is known to be, in the vast majority of instances, most prejudicial, and even fatal. But the moderate use does not seem at all incompatible with the most robust health.

Still, even allowing for the influence of habit, it is scarcely possible but that its most moderate use entails some effect, and in some way modifies nutrition; and later physiological researches render it not improbable that these results may speedily be laid open to our view. In the meantime, what is, perhaps, most wanted, is a strict comparison of the total abstainer with the moderate user of alcoholic fluid; and, in order to this, so close a similarity is required, that it can scarcely be attained by the comparison of individuals; but, like the great problem of health generally, must be worked out in numbers and masses. At present, Jonadab, the son of Rechab, and his teetotal descendants, are worn quite threadbare by perpetual quotation, and really require rest, if not superannuation. And the teetotallers of modern times are, as yet, scarcely a proper basis for calculation; although, both as regards the perfection of their health and their immunity from disease, grave suspicions are even now entertained by some observant members of the Profession.

In working out this question, we cannot too constantly bear in mind the physiology of civilization—especially in nations like our own, in which the body, subjected to the severest mechanical toil, is associated with an intellect whose responsibilities and exertions raise it far above that of the savage; and all this in the midst of physical circumstances which are always unvarying, often unvaryingly wretched. A large proportion of our population labour for a long series of hours in mechanical drudgeries, which occupy the body without the mind, and leave them utterly exhausted; while their position, or habits, or tastes, deny them many of the endless varieties of nature which would form the best relief to their lassitude. Under these circumstances, the desire for mental relief, amusement, and excitement, takes some other form, and amongst natural agents a stimulant is eagerly sought after, to remove the pain of mental exhaustion and anxiety. At present, excise regulations and adulteration render tea and coffee diluted and innocuous, public opinion checks opium, and somewhat moderates the use of tobacco. But the physiologist knows, that all of these substances, to be agreeable by their moderate influence, must be poisonous in a larger dose: and, unless a man be absolutely prepared to forego every one of them, he may be a man of taste in preferring the least intoxicating, a man of prudence in selecting the least hurtful, and a man of feeling in preferring that by the general use of which the least mischief would be done; but he steps beyond mere nutrition and the more obvious exigencies of his system, and has no right to affect the character of a hero of self-denial.

Probably, in an ideal human existence, all such stimulants are utterly unnecessary, and, so far as they have any perceptible action, are hurtful. But it has yet to be inquired, whether their moderate use does not directly or indirectly enable a greater amount of work to be performed, with less harm to mind or body than would otherwise result. And, if this be the case, while the effect of excess is a question which need not be entertained for an instant, it may teach us to moderate our clamours against the moderate use of any one of them, and direct more attention and exertion towards the removal of the evils which recommend their immoderate use; viz., overwork of mind and body, insufficient or improper food, and deficient air and light.

Under any circumstances there would, perhaps, be some found who distinguish between use and abuse,—between the wine which "maketh glad the heart of man," and the overdose of the same fluid which "biteth like a serpent and stingeth like an adder." There may be reasons of convenience and philanthropy, which would induce such to abstain, and, in the latter case, all honour be to their feelings. But, on medical grounds, and viewing society as it is at present constituted, we are scarcely as yet entitled to denounce the moderate use of alcoholic beverages as necessarily hurtful; or if so, we cannot isolate them in this respect from many other stimulants.

On the whole, considering the condition of the labouring classes, this question ought to be regarded as forming but a small part of a great sanitary movement, upon which it is in a great measure dependent, and without the progress of which, the mere discountenancing of a particular stimulant would be doubtfully prudent, and certainly futile.

THE QUEEN'S COLLEGES IN IRELAND.

During the Viceroyalty of the Duke of Rutland, the Irish Parliament being at one time in a mood of peculiar philanthropy, voted a sum of money for the erection of fountains in the city of Dublin, to supply water gratuitously to the poor. This money was placed at the disposal of his hilarious Excellency, who was entrusted with the selection of the most appropriate sites, and the various executive details. The fickle Viceroy at once proceeded to obtain plans and estimates, selected the most gorgeous and expensive, and fixed on the most fashionable localities in the city for the contemplated eleemosynary erections. It was true that the chief squares and first-class streets were not exactly the districts in which the poor were principally congregated, and it would have been manifest to any judicious mind, that the whole utility of the grant was neutralized by such selection; but that was not the consideration which arose in the minds of the aristocratic inhabitants of the vicinity; the inconvenience they dreaded was not to the poor, but to themselves; and the congregations of ill-dressed and squabbling room-keepers, crowding with pitchers and kettles before their very windows, affected their imagination as the worst of conceivable nuisances. They accordingly represented their apprehensions to the Lord-Lieu-

tenant, and he, good-natured man, immediately sympathised with their feelings, and promised that the fountains in course of erection, while they should be ornaments, owing to their elaborate architecture and sculpture, should never be the slightest annoyance, for he would take care that they should be always *dry*. This sage resolution was accordingly adhered to; and there stands at this moment in Merion-square a "fountain" gracefully designed, and richly ornamented with tablets of the purest marble, erected out of funds originally devoted to the benefit of the poor, but from whence, to this moment, a drop of water has never flowed.

History has been said to be "an old almanack;" and certainly, year after year, and century after century, present to us events, which, however varied may be the circumstances, are nevertheless very analogous in their essential characteristics. It may be an Imperial and not an Irish Parliament that is now legislating for the sister kingdom; the object may be to supply education, and not a mere physical requisite to the Irish people; but it is as necessary at this day as in the times of His Grace of Rutland, that the acts of the Local Executive should be closely scrutinised, lest the munificent intentions of the Legislature should be frustrated, and the fountains of knowledge be kept always *dry*.

We have been led to these reflections by an examination of the names, recently published in the *Gazette*, of the gentlemen selected by the Lord Lieutenant of Ireland to fill the various Professorships in the three new Colleges recently founded in Belfast, Cork, and Galway. We stated, on a former occasion, our opinion of the great responsibility imposed on His Excellency by the necessity of making these appointments. The success or failure of a gigantic speculation, on which the British Parliament has already expended 120,000*l*., and has incurred a liability of 20,000*l*. a year for its continuance, mainly depended upon the honesty and judgment with which the claims of the various candidates were sifted. But the magnitude of the funds hazarded can afford but a very feeble indication of the greatness of the interests at stake. It is manifest, that the success of an experiment so costly, and connected with such important interests, could only be insured by the employment of the very best materials. We consider it to be the wisest economy to employ adequate means to gain the end in view. Expecting the Irish Executive to be guided by this principle, we have carefully studied the appointments to the Medical Professorships in the New Colleges, and we regret to say, that the result of our examination has been a sense of profound disappointment. We do not mean to assert, that the new Professors are other than respectable men in all the relations of private life; nay, the greater number of them might, in routine circumstances, or in slight difficulties, fulfil the duties of their position in a creditable manner; but the conditions amidst which they are placed are not ordinary: they are required not only to teach, but to excite a disposition to be taught; not merely to gratify, but to create an appetite. We take it, that the purpose of the Legislature, in founding these New Colleges in Ireland, was to set up there luminous founts, from whence the light and warmth of useful knowledge might flow over the length and breadth of the island, diffusing amongst the middle and upper classes, without distinction of creed or party, a delight and skill in those sciences and arts whose cultivation best conduces to social prosperity and happiness.

We have no desire to comment on any of the new appointments, except those immediately connected with the Medical Profession; we shall, therefore, confine our remarks to those appointments which, being more immediately connected with medicine, are of chief concern to our readers and ourselves. The following list contains the Medical Staff of the three new Colleges:—

BELFAST.

Anatomy and Physiology.—Alexander Carte, M.D. F.R.C.S I.; late Demonstrator of Anatomy in Trinity College; and Conservator of the Museum in the College of Surgeons in Ireland; author of Papers on anatomical and surgical subjects.

Practice of Surgery.—Alexander Gordon, M.D., Honorary Member of the Royal Physical Society of Edinburgh; late Professor of Surgery in the Royal Belfast Institution.

Practice of Medicine. John C. Ferguson, M.D., late Professor of the Theory and Practice of Medicine to the King and Queen's College of Physicians; Physician in Ordinary to Sir P. Dunn's Hospital; Author of "Contributions to the Literature of Medicine."

Chemistry.—Thomas Andrews, M.D., F.R.S., M.R.I.A., Vice-President of the Queen's College, Belfast.

Natural History.—George Dickie, M.D., Lecturer on Zoology and Botany in the University and King's College of Aberdeen; Author of numerous contributions to botanical science, published in various scientific periodicals.

Materia Medica.—Thomas O'Meara, M.D., formerly University Medical Scholar of the University of London.

Midwifery.—William Burden, M.D., Physician to the Belfast Lying-in Hospital; late Professor of Midwifery in the Royal Belfast Institution.

CORK.

Anatomy and Physiology.—Hugh Carlile, M.D., late Lecturer on Anatomy and Physiology in the Park-street School of Medicine, Dublin; formerly Anatomical Assistant to the late Professor Macartney.

Surgery. Denis B. Bullen, M.D., one of the Surgeons to the North Infirmary, Cork; Author of a Work on Cholera, and of Communications to the Medical Journals.

Practice of Medicine.—D. C. O'Connor, M.D., Physician to the Workhouse, Cork.

Chemistry.—J. Blyth, M.D., late Professor of Chemistry in the Royal Agricultural College, Cirencester; Author of *the* Work on Chemical Analysis for the use of Agricultural Students, and of Original Memoirs on Chemical Subjects, published in the Scientific Journals of Germany and England.

Natural History.—William Hinks, LL.D., formerly Professor in the Manchester College, York; Author of Original Papers in Botanical Science.

Materia Medica.—A. Fleming, M.D., Author of a Treatise on the Aconitum Napellus, and Communications to the *Monthly Journal of Medical Science*.

Midwifery.—J. A. Harvey, M.D., Physician to the South Charitable Infirmary, Cork.

GALWAY.

Anatomy and Physiology.—Croker King, M.D., M.R.I.A., F.R.C.S.I., Professor (Honorary) of Anatomy to the Royal Dublin Society, and Demonstrator of Anatomy to the University.

Surgery.—James V. Brown, M.D., Member of the College of Surgeons of Ireland, A.B., T.C.D.

Practice of Medicine.—N. Colahan, M.D.

Chemistry.—E. Ronalds, M.D., Lecturer on Chemistry in the Middlesex Hospital; Editor of "Knapp's Applied Chemistry," and of the *Journal of the Chemical Society*.

Natural History.—A. G. Melville, M.D., formerly Demonstrator of Anatomy to the University of Edinburgh; Author of a Work on the Dodo and its Kindred, and of several papers on subjects of anatomy, &c.

Materia Medica.—Simon M'Cay, M.D., Lecturer on the Theory and Practice of Surgery, and Examiner in Materia Medica in the Royal College of Surgeons, Author of Notes of Dr. Collis's Surgical Lectures, and of Papers on Medical and Surgical subjects.

Midwifery.—No appointment.

Our readers will be amused, we feel no doubt, at the additions to the above names, which beat anything similar in the *London Medical Directory*. Of the veracity of these appendages, a very good example is exhibited in the qualifications added to the last name in the above list. Would not any one imagine from the wording of the passage, that Dr. M'Cay was lecturer on the Theory and Practice of Surgery in the Royal College of Surgeons? whereas, the fact is, that this gentleman simply lectured on Surgery in a little private school, set up by himself, and which school perished, some twelve or fourteen years ago, of a rapid consumption, after a very brief existence. And, again, credit is taken for his being the "Author of Notes of Dr. Collis's Surgical Lectures!" What would be thought of a reporter of the *Medical Times*, seeking for a Professorship in King's College, or University College, on the ground of his having reported Mr. Liston's lectures? Yet the case is precisely parallel. We take this case merely as an example, for we are quite sure, that Dr. M'Cay had nothing to do with the trickery and misrepresentation to which we have alluded.

The first thing that will strike any one who attentively peruses the foregoing list, will be the large proportion of local physicians and surgeons that have been appointed to the various Professorships. In Belfast, the chairs of Surgery, Chemistry, and Midwifery, have been filled by the former occupiers of the same chairs in the Royal Belfast Institution. In Cork, the chairs of Surgery, Practice of Medicine, and Midwifery, have also been bestowed on resident Practitioners; and, in Galway, two of the local doctors have been made Professors of the Theory and Practice of Surgery and Medicine. If the Medical Men of a provincial town are qualified to lecture, and can get classes to attend them, we do not see why they should be prevented; and, in accordance with this opinion, the various licensing bodies are in the habit of recognising, under certain regulations, certificates from Provincial Schools. Such schools have for some years existed in Belfast and Cork. The former, we believe, has had a fair class of students; and, if the latter failed, it was because of the incapacity of the teachers; for in the instances in which the lecturers were worth listening to, the classes were always large. Still it must be acknowledged, that Provincial Schools labour under considerable disadvantages, one of the chief of these being the want of an adequate field for clinical observation. This is an inherent inferiority which Provincial Schools labour under, when compared with Metropolitan; and one that cannot be removed by Parliamentary Grant or Royal Charter. Lectures and Museums are of little utility in the education of the physician or surgeon, unless the students have also sufficient opportunities of studying the phenomena of disease by the bedside. If the medical schools of Belfast or Cork are capable of competing, on equal terms, with those of Dublin or London, and of furnishing adequate clinical instruction, there can be no necessity for Governmental

interference. Our present Premier has declared himself an advocate for the policy of *laissez faire;* and in no case is that policy more imperatively demanded than in this. To bolster up, by Government grants and patronage, bad or inferior Medical Schools, is to rear up for the service, or rather injury of the public, a bad or inferior race of Medical Practitioners. If the Professors of the Belfast Institution have proved efficient and successful teachers, they have their reward, but have no peculiar claims to being created Royal Professors and pensioners on the public purse.

But if the local Practitioners in Belfast, Cork, and Galway are to be converted into University Professors—if the claims of the Colahans, Browns, Bullens, O'Connors, and Harveys are to be preferred to those of men who have distinguished themselves in Medical and Surgical Science, because they are local Practitioners, and because the introduction of rivals from the Metropolitan Schools, of men who might compete with them, and perhaps supplant them in the emoluments of practice, would be a grievance and a wrong,—if that be the rule by which the Executive had resolved to be guided, how are we to account for the exceptions? Dr O'Connor in Cork, and Dr. Colahan in Galway are considered to be good enough to be made Royal Professors of Physic. Was there no one in Belfast fit to occupy a parallel position? Why should Dr. Ferguson be transferred from the peaceful bowling-green of Trinity College, Dublin, to the lecture-hall of the northern Metropolis? We doubt much if the members of the Belfast Pathological Society will approve of this distinction which has been made between the Practitioners of their loyal city, and those resident in the capitals of the south and west nor will their sense of wrong be diminished by the recollection, that the gentleman thus sent down to supersede them, had earned a title to Government reward, as early as 1817, by being the first to accept, in the teeth of his Professional brethren, the remuneration of five shillings per day, proffered by the Board of Health for attending fever patients.

When it was first announced that Medical schools were to be attached to the new Colleges, the Dublin teachers got into a panic; they feared that this new competition, supported by Government, would seriously injure the Dublin School of Medicine. A meeting was called, and a deputation waited upon the Viceroy, to represent the mischief about to be inflicted; and it is said, that His Excellency listened attentively to the complaint preferred, and promised to inquire into the matter. We have not been told that the Earl of Clarendon positively promised to obviate any injurious rivalry on the part of the new schools; but if he did, sure we are, that he has effectually kept his word. Like his predecessor, to whom we have alluded in the commencement of this article, he has erected beautiful buildings calculated to adorn the localities in which they are placed; but, just as the Duke of Rutland took precautions to keep his fountains "dry;" so has the Earl of Clarendon, by his Medical Professorships, rendered it certain that the Medical schools attached to the Queen's Colleges in Ireland shall remain without pupils.

THE OPERATIVE SURGERY OF JOHANN FRIEDRICH DIEFFENBACH.

Edited by
J. STEVENSON BUSHNAN, M.D.,
Fellow of the College of Physicians of Edinburgh;
And
ALEXANDER URE, Esq.,
Fellow of the College of Surgeons of England, and Surgeon to the Westminster General Dispensary, &c.

(Continued from page 125.)

CHAPTER III.
CAUTERIZATION.
Ustio, Cauterisatio.

Cauterization is produced either by means of medicaments which decompose the organised textures, (*cauterium potentiale,*) or by burning, (*cauterium actuale.*)

THE POTENTIAL CAUTERY.

Caustic is employed in a solid or liquid state, or in the form of a paste, a salve, or a powder. If applied in a dilute state, so as not directly to destroy the surface, it determines an alterative or a diffuse but superficial decomposing effect.

Caustic is used particularly for eroding the flesh in the instance of envenomed wounds, (but here excision is preferable, because, as formerly mentioned, the resulting eschar is apt to retain the poison in the system,) in superficial parenchymatous hæmorrhage, in callous ulcers, in cutaneous cancer, in lupus, in variola sanguinea, and in chronic abscess, either in the form of a solid cylinder, for the purpose of making an opening, or in that of a liquid, for throwing into the secreting cavity; or like an injection into serous cysts, as hydrocele; also for making issues; as a stimulant where the edges of the skin are flabby and suppurating, or to incite inflammation in parts still covered with epidermis, so as to favour coalescence, as, for example, in cleft palate.

The usual caustics are nitric acid, sulphuric acid, sulphate and acetate of copper, chloride of antimony, potassio-tartrate of antimony, nitrate of mercury, bichloride of mercury, red oxide of mercury, chloride of zinc, nitrate of silver, quicklime, hydrate of potash and arsenic; to these may be added concentrated tincture of cantharides as an excellent medicament for promoting vigorous granulation.

The action of caustics is very variable, partly owing to their nature, the mode of application, and the parts with which they are brought in contact. When used in a liquid state, the moist surface, as, for instance, that of an ulcer, must be previously wiped dry with picked lint, to prevent overspreading. In parenchymatous hæmorrhage the blood must be repeatedly taken up with a sponge, and the solid caustic applied at short intervals. Dry escharotics require the intervention of moisture. In order to protect the adjunct parts against excoriation from liquefaction of the caustic they may be smeared over with an ointment composed of two parts of wax with one part of oil, or bound with a piece of plaster having a hole in the centre, provided the caustic melts slowly, applying the same ointment beyond and a dossil of lint on the top to imbibe any fluid exudation.

1. *Liquid Caustics.*—Those most frequently resorted to are sulphuric acid, concentrated solutions of hydrate of potash, and of nitrate of silver. After the surface has been previously cleansed, and the vicinity sheltered against any diffusion of the medicament, the application may be made, with a pencil of spun glass attached to a glass tube.(a) This obviates all chance of chemical decomposition and impurity. At the outset, the surface ought to be touched very gently; but, after dabbing on a little picked lint, it may be re-touched more freely with the corrosive. Dilute solutions, which act gradually, may be applied with a dossil of lint, but for shallow ulcers, small portions of thick twilled calico are preferable. For sinuous ulcers plugs of lint, of a suitable length and thickness, after previous moistening with the solution, may be introduced with a whalebone probe. The alteration produced on organic textures by different caustics is very variable. Nitric acid occasions a yellowish white, muriatic acid a hard white, and sulphuric acid a dirty brownish black scar.

2. *Soft Caustics.*—Escharotics, in the form of salve or paste, act more slowly and profoundly than in that of liquid, even though the basis be the same. Arsenic has long been held in high repute as a remedy in cancer, not merely on account of its topical escharotic power, but from its exercising an alterative influence over the adjunct parts, and thereby insuring a longer respite from the ravages of that intractable disease, than most other medicinal agents of the class. Its employment ought, however, to be restricted to small superficial affections, as, for example, cancer of the skin and lip, and to obstinate ulcers, which sometimes occur at the roots of the nails. When the cancerous malady is extensive, as in scirrhus of the breast, arsenic is both inefficient and dangerous. As a general rule, it ought never to be applied to a bleeding surface.

White oxide of arsenic, or arsenious acid, rapidly destroys the parts with which it is in contact, and causes a severe and abiding sensation of pain, which does not abate until the flesh has become dead and arid like that of a mummy. The fantastic formula of Frère Cosme, which is still in vogue with some Continental surgeons, is as follows:—Take of vermillion 2 drachms, the calcined soles of old shoes 8 grains, dragon's blood 12 grains, white arsenic 2 scruples; triturate together into an impalpable powder. A paste is made by adding a little water to a certain quantity of this powder, which is pencilled over the surface of the ulcer, and a piece of lint super-imposed. It is allowed to remain until a complete slough is formed. The resulting sore is afterwards dressed with an ointment consisting of equal parts of almond oil and white wax spread on lint. If the process of granulation be languid, a little levigated red precipitate may be dusted over the surface by way of an alterative. I cannot too strongly caution young practitioners against adopting this mode of treatment for large malignant ulcers. I have witnessed the death of a female in consequence of having had an injudicious quantity of the arsenical paste applied to an open cancer of the mamma. In delicate persons, also, even after the most careful employment of the medicament, symptoms of poisoning have been known to supervene. Under such circumstances, the application ought to be removed forthwith, some bland dressing substituted, and the appropriate antidotes administered by the mouth.

Hellmund's modification of Frère Cosme's paste is thus prepared:—Take of vermillion half a drachm, the calcined soles of old shoes 3 grains, dragon's blood 4 grains, white arsenic 10 grains; reduce the whole to an impalpable powder. Take of Balsam of Peru, extract of hemlock, each one drachm, acetate of lead one scruple, laudanum half a scruple, cerate one ounce; mix together so as to form an ointment. Half an ounce of the above ointment, combined with half a drachm of the powder, is spread upon lint, which is cut into small squares, and thus applied to the diseased surface previously wiped dry, and made to include a portion of the healthy circumference. The whole is covered with picked lint and strips of plaster. After the separation of the slough, the sore is treated in the manner above described. Dupuytren recommended a powder composed of 1 grain of arsenious acid to 99 of calomel, for superficial sores of the face; Rousselot one containing 8 parts of arsenious acid, 22 parts of dragon's blood, and 70 parts of red precipitate.

(According to Christison,* absorption seems less likely to occur when a strong arsenical mixture is used, containing one-tenth, or even one-fourth part of its weight of arsenious acid, than when the weaker mixtures are applied, which are made use of generally on the Continent. A convenient mode of applying it is to form it into an ointment with

(a) I have been in the habit of employing a pencil of this description, furnished by Messrs. Bell, of Oxford-street.—A. U.

Dispensatory, p. 185.

lard, or into a paste with conserve of roses, thickened, if necessary, with powder of gum, and to add some powder of opium, to allay the pain).

Chloride of zinc has, in a great measure, superseded the arsenious acid as an escharotic. It is now extensively applied, in the form of paste, not merely to cutaneous carcinoma, but occasionally to cancer of the mamma. Canquoin suggested its admixture with wheaten flour in different proportions. Thus, his paste No. 1 is composed of one part of the chloride with two parts of flour; No. 2, of one of the chloride with three of flour; and No. 3 of equal parts of each. The powder is mixed with a few drops of water, then set aside in order to attract additional moisture, which renders it soft and plastic. To augment the suppleness of the paste, one part of chloride of antimony is sometimes conjoined with two parts of chloride of zinc.

[As the wheaten flour prescribed in the above formulæ is apt to envelope the chloride in a glutinous dough, which tends to blunt its power, or at any rate to confine its action to the particles on the surface of the paste, I have been in the habit of substituting a portion of anhydrous gypsum in its stead. This, while it can exercise no chemical action upon the chloride, forms a porous medium, through which the particles of the deliquescent chloride may transude upon the morbid surface, with the effect of decomposing or destroying it with certainty to any definite depth.

When the integuments are sound they may be removed by means of a blister, and on the following day one or other of the above preparations, corresponding to the thickness of the tissue to be destroyed, is to be applied to the cutis of the diseased part. I have generally employed, as more convenient for this purpose, the caustic ammonia or hydrate of potash.

The depth to which it will corrode the morbid texture can always be estimated beforehand; its action is unfailing, and the eschar is separated in most cases from the 8th to the 12th day, coming away quite entire in the form of a whitish-gray mushroom-like substance, and leaving behind a singularly healthy sore, which heals with great rapidity. In numerous instances, where I have applied it very largely, I have never known it productive of constitutional disturbance. The pulse remains natural, and the skin cool. Yet it acts as a powerful local stimulant, causing swelling, redness, and pain. The last is of a violent burning character, persisting, with great intensity, for the first eight or nine hours; after that time, *i. e.*, when the surface is fairly eroded, it becomes supportable, as the patients express it, and continues so during the remainder of the application of the remedy. An important point is, that the pain is in a great measure under the control of opium, a full dose of that drug previously administered seldom failing to give great relief.

From considerable experience in its use I am disposed to conclude, that it is chiefly efficacious in those so-called semi-malignant tubercles and ulcers which make their appearance about the face of persons advanced in life, where the skin is involved, but without any depth of new structure; in the circumscribed tubercle of the cicatrix following operations for cancer, in a form of lupus, which I have described (a), as the erosive ulcer of the follicles of the skin, in superficial ulceration of the neck of the uterus, and in nævus maternus. In true carcinoma affecting glandular and fleshy parts it will only effect temporary melioration. See article "Caustics" in "Cyclopædia of Surgery."—A. U.]

3. Solid Caustics. Those most in repute are nitrate of silver and hydrate of potash. Both coincide in that they rapidly and completely destroy the vitality of the soft organized textures, inducing gangrene, but in different ways. Thus the former determines dry, the latter moist gangrene. The caustic potash causes a liquefaction of the organic substance, with which it combines so as to form a kind of dark smeary soap; the lunar caustic, death of the part, followed by a black, mummy-like desiccation, resembling senile gangrene. The potash, from i liquescency is advantageously resorted to in cases malignant pustule. Here it was employed by Dupu tren in the form of troches. The same surgeon als had recourse to it for cauterizing the neck of the uteru when affected with carcinoma; he previously intro duced a speculum, and with a dossil of lint held i forceps, carefully dried the part. After the appl cation, a round soft compress was passed up th vagina, and then the speculum withdrawn. Th caustic, however, is not well adapted for the abov purpose, from its proneness to spread. Lisfran gave the preference to nitrate of mercury dissolve in nitric acid. The most exact way of man pulating the potash is to fit the fused cylinde within a glass tube, and by means of a probe passe up from the opposite end to keep it in appositio with the integument, or morbid surface. The slim shreds are wiped away with a soft rag, and afte enough caustic has been expended, the spot covered with lint, and the adjoining skin with plaste or mild dressing to prevent excoriation. It is gene rally preferred for forming issues; and the most con venient mode of employing it for that purpose is t apply to the skin one or more layers of linen sprea with adhesive plaster, having a circular opening i the centre, corresponding to the intended size of th issue, and then to rub upon the skin, within th opening, a piece of the caustic previously moistene at one end. The application is to be continued til the life of the part is destroyed, when the causti should be carefully washed off. Poultices are afterwards to be applied till the separation of the escha is effected. As a general rule, in using this caustic owing to its diffluent tendency, the erosion of th sound integument ought to occupy a narrower com pass than that of the eschar about to be formed.

The so-called Vienna caustic is composed of fiv parts of hydrate of potash and six parts of quick lime. The mixture is kept in a phial. When in tended for use it is made into a paste with spirit o wine. In this state it determines a speedy disor ganization of the part, which is afterwards to b washed with water and vinegar. If a very energeti effect is desired, it may be allowed to remain on fo twenty minutes. The advantage of this compound is, that the quicklime serves to absorb any redun dant moisture, and thus set bounds to the escharotic action.

Nitrate of silver, or lunar caustic, is in the hands of every surgeon. On a granulating surface it produces a whitish film; but if applied more freely a kind of mummy-like transformation of the anima textures. Its operation does not extend to any con siderable depth; and the separation of the eschar does not take place for several days, owing to the small amount of re-action in the adjunct parts. It is sometimes used to form an issue. For this purpose a piece of plaster, with a flap cut in the centre, is placed on the skin, within which, after previous moistening, a fragment of caustic the size of a pea is inserted, and secured by means of square adhesive strip, compress, and roller.

II. THE ACTUAL CAUTERY.

The agency of heat at various degrees of temperature is employed in the treatment of disease. Thus, hot water, steam, heated air, fire itself, and ignited iron, have been severally resorted to by surgeons. While disposed to censure much that has been recommended under this head, such as the practice of injecting boiling water into sinuous canals, and that of indiscriminately searing diseased joints, I strongly advocate the utility of the actual cautery in particular instances. Thus, in perilous hæmorrhage within cavities, as for example in the throat and dental alveoli, it can seldom be dispensed with; as also in bleeding fungus, hospital gangrene, carbuncle, organic defects and palsy of the encephalon and spinal marrow; it is inadmissible, on the other hand, in nævus or erectile tumour, or the bite of a rabid animal, from the risk of the eschar keeping the poison pent up in the system. Burning ought never to be employed with children, because it is most dangerous, often more so indeed than the malady, and prone to induce trismus and other nervous affections. It is well known, that many a child has died from a scald of the hand.

Cauteries are of different dimensions. Thus, there are the small, the middling, and the large. The smallest are not bigger than a lentil; the largest have a head weighing from half a pound to a pound. The instrument consists of three portions; the head, or button, which is the essential, the stem, and the wooden handle. The first is variously fashioned, but the two last are tolerably uniform as regards shape; although it is obvious, that the iron employed for searing a carious tooth, must have a smaller stem and handle than one for cauterizing the haunch. Among the divers forms may be mentioned, that of the lentil, the olive, the disc; and lastly, the forked, tubular, annular, conical, cylindrical, and prismatic irons.

The surgeon, before applying a large-sized cautery, ought either to administer some anæsthetic agent, or else have plenty of assistants at hand to control the struggles of the patient; otherwise unintentional injury may be done.

The patient is couched upon an operating table or a sofa. The irons, heated to incandescence in an adjoining apartment, are to be handed to the operator, out of view of the patient. For the purpose of checking hæmorrhage, the button ought to be rounded or ovoid, of a bulk commensurate with the surface to be touched, the neighbouring parts being protected by dry or moist folds of linen. If the mouth be the seat of the bleeding, the individual should sit up, and before each introduction of the cautery, a large dossil of lint, held in forceps, is to be passed round, the lips and cheeks being shielded as above stated. Here, however, folds of dry linen are preferable to wet, as tending to conduct the heat less rapidly. If it be an extensive bleeding fungus, the iron must be proportionately large, thick, and slightly rounded, the patient reclining, and the contiguous surface strewed with pulled lint to absorb the blood.

For the production of a deep issue, a spherical or bung-shaped iron is most eligible. Hæmorrhage from the anus is not to be arrested by searing, but by plugging, which is exempt from danger. In cauterization of cancer of the rectum, the anal orifice must be slit before and behind, and a plum-shaped iron introduced along a horn speculum; a larger speculum of the same material is employed for the vagina. Tubular shields, made of tin plate, are hazardous because the least touch of the hot ron causes the tin to melt, run into, and scath he mucous membrane. In cauterizing an articulation, the streaks are to be made longwise, of from a third of a span to a span in extent, all the way round, with a prismatical iron. If it be the houlder or knee-joint, the patient is to lie on his is back; if the hip joint, upon his belly. The ron is passed equally along with a steady hand. The anterior part of its extremity ought to be omewhat turned up, to prevent its hooking in the lesh. If moved too rapidly it does not penetrate ufficiently; too slowly, it is apt to press injuriously, upture the skin, and cause a gaping wound. This, fat persons, is apt to be followed by protrusion of the subcutaneous fat, and in lean by lamage to the fibrous textures underneath. From wo to six streaks generally suffice, and for every wo a fresh iron is required.

After the operation the patient is put into bed, nd the burnt surfaces covered with cotton wadding, is the best means of allaying the pain.

The cauterized streaks present a brown, black, and yellowish-grey aspect, surrounded by a red ireola. The resulting eschars are not usually detached before some weeks have elapsed. Should he suppuration be scanty, stimulant dressings are o be applied; should, on the other hand, the granulations be too luxuriant, shreds of twilled calico, soaked in solution of nitrate of silver.

The application of the hot iron, *par distance*, or its fleeting transport from one point to another, *cauterization transcourante*, is of very little use.

MOXA.

Moxa signifies a burning cylinder. It is of exotic origin, having been first introduced from

(a) *London Medical Gazette*, Vol. XIX., p. 328.

Asia into Europe, and of very ancient date. It has the form of a candle end, and varies in thickness from that of a small wax, to that of a carriage light. It ought to burn equably from above downwards, that the glowing surface may advance steadily towards the skin, and leave behind no cinder.

Moxa is composed of some combustible substance—charcoal-pastille, touchwood, the pith of the Helianthus, amadou, and cotton wool, have each been used for the purpose. The last is to be preferred. A moxa prepared with cotton wool, previously imbued with solution of nitre, and dried, burns quite away. A simple cylinder of raw cotton, loosely packed, will suffice, but, when once kindled, requires a stream of air directed upon it to maintain combustion. Pouteau fashioned his moxa by sewing up a round roll of cotton wool in linen, so as to resemble a thin rouleau, and cut it into pieces of a suitable length. For keeping it in its proper position, Larrey contrived a small brass ring-trivet, with wooden feet and handle. But nothing answers better for fixing the cylinder, and also protecting the surrounding integument, than a bit of moist pasteboard, with a hole cut in the centre to the right size. Some authors recommend the employment of a blow-pipe or bellows for insufflation; but their action is too powerful, and the moxa never burns so uniformly as when merely blown by the mouth.

In burning with moxa, the patient is to lie on a sofa with the part placed horizontally, to prevent the cylinder falling off. The moxa, fixed in its pasteboard disc, is then applied to the skin, and retained *in situ* by an assistant, while the patient is supported by two other assistants (unless under anæsthetic influence). The operator kindles it at the top, and continues to blow gently until all is consumed. The scar, which has the appearance of whitish-grey leather, encircled with a reddish zone, is then cleaned with a dossil of picked cotton wool. Cotton wadding furnishes the most comfortable dressing. Neither cold water nor oil should be applied; the latter greatly aggravates the pain. Several moxas may be used in succession, according to the exigency of the case; as, for example, over the surface of an extensive chronic abscess. As a topical remedy, moxa is superior to the actual cautery, both in the above-named instance of chronic abscess, and likewise in that of paralysis, because it exercises a particularly stimulating effect on the nervous system.

The separation of the eschar is somewhat tardy, depending partly on the constitution of the patient, the size of the moxa, and the part implicated. Here emollient poultices are beneficial. The raw surface is either to be healed up with bland dressing, or else treated as an artificial sore, and secretion encouraged by the aid of irritant unguents or issue peas.

Cauterization with potassium, phosphorus, or burning-glasses, is not commendable.

REVIEWS.

Oratio ex Harveii, Instituto in Ædibus Collegii Regalis Medicorum, habita Pridie Calend. Julii, A. D. 1849. A JOHANNE CARR BADELEY, M.D., Cantab. Coll. Reg. Med. Londinensis Socio.

The name of Harvey is associated with much that is interesting to the English Medical Profession. Born in an age in which science had only just commenced her struggles for freedom after a bondage of many centuries, it was his privilege to assist in effecting her emancipation. Like many great men who had preceded him, he lived in advance of his own age, and consequently his brilliant discoveries only drew down upon him the indignation of the "vulgar herd," incapable of appreciating the greatness of the man. Harvey knew the value of his own discoveries, and the waywardness of public opinion; and hence he was supported by the conviction, that if his contemporaries failed to do him justice, posterity would. The instances are but comparatively few in which Nature and Providence unite to form the truly great and extensively useful. In Harvey we have one of those instances. Nature had endowed him with an exalted intellect, and Providence had blessed him with an ample patrimony: he freely consecrated both to the service of mankind. Like a true philanthropist, persecution did not make him swerve from his benevolent work; and the very Oration which bears his name, and is annually delivered at the College of Physicians, is a perpetual memorial of his disinterested love for the Profession of which he was so honourable a member.

It is a singular circumstance, that the College which Linacre founded for the promotion of medical science, and Harvey endowed, should, in its infancy, have become a persecutor of those whom it ought to have protected. That the establishment of this Institution was imperatively called for by the state of the times, none can reasonably doubt. "Enim," as Dr. Badeley appropriately remarks at the commencement of his oration, "Eo sæculo, et Monachi et Empirici medendi artem latè exercuerunt; et Episcoporum erat hos ψευδο ιατρους perscrutari." Hence Linacre wisely judged, that taking from the Bishops the power of licensing Physicians, and conferring it upon a medical Corporation, would do much to keep down ψευδο ιατρους. Would that this College had been all that its founder desired it should be! Harvey discovered to his sorrow, that Colleges established for the express purpose of furthering science often but imperfectly accomplish this end. Yet his magnanimity was such, that forgetting his own wrongs, and hoping the College might eventually become a nursing mother of science, liberally endowed that College out of his own patrimony. Dr. Badeley adverts to Harvey's labours, persecutions, and fortitude, in the following manner:—"Altior rerum ordo cum illo natus est, qui post tot annos in medicinà promovendà elapsos, fontem reclusit è quo aureum scientiæ flumen patriam populumque ditavit! Nimirùm ille qui per corpus sanguinis circuitum detexit, ad morbos corporis sublevandos novam et adhuc inculcatam semitam nobis patefecit! Ecquis enim vel febrem, vel phlogosin, nisi empiricè, hâc absque notitiâ, tractare potuit? Ecquis de cordis motu, circulationis nescius, judicare ausus est? Hoc omne detexit Harveius—hoc omne experimentis probatum, et oculis aliorum fidelibus eo tempore honestè subjecit, et natis 'natorum, et qui nascentur ab illis' in lucrum tradidit! Hinc vero ortus est improbus et ineptus clamor! Invidiæ veneno afflati non deerant, qui palmam Harveio debitam vel sibimet ipsis arrogare, vel aliis coronam eam triumphalem imponere, inhonestè certabant—inter quos Riolanus, et Parisanus, et Servetus, et Columbus, et Cæsalpinus, cum multis aliis enumerandi. Qualiter tamen cursum suum ordinatum Luna tenet, canesque qui vano se latratu lacessunt, cum fastu aspernatur; 'Pergant,' respondit Harveius, 'pergant maledicendo; donec ipsos, si non pudet, pigeat tædeatque!' Contra enim vero veritatem quàm futilis contentio! 'Merses profundo, pulchrior evenit' et palmam quam meruit, postremo Harveius, et in æternum, credite, laturus est."

In this Oration, Dr. Badeley pays a just tribute to the memory of many deceased Physicians, and stirs up his young brethren to follow in the footsteps of those who were "burning and shining lights" in their generation. Towards the close of his discourse, he adverts in terms of commendation to those eminent Practitioners, who are now in various departments of their Profession attaining a high position. We wonder, however, what the stethoscopists will think of the manner in which the Orator speaks of their favourite instrument "qui Stethoscopi nomine *gaudet*?" We think Dr. Badeley has given them a gentle rap, cum "Caduceo Apollineo," and we hope for this the sons of Apollo will not do to the orator as the god did to the fiddler for challenging him at music—skin him alive!

The Oration, which exhibits the Author as an accomplished scholar, finishes with a tribute of praise to the College, for the spirit of liberality it now manifests:—"Latius hujus templi pandantur portæ, adeo ut quæcunque sit Alma Mater, sive sit Oxoniensis, sive Cantabrigiensis, sive Londinensis, sive vel Edinensis vel Eblanensis, filii cujusque, (sint modo digni,) nos inter recipiantur."

The Three Kinds of Cod Liver Oil, comparatively considered with reference to their Chemical and Therapeutic Properties. By L. J. DE JONGH, M.D., of the Hague. Translated from the German. With an Appendix and Cases. By EDWARD CAREY, M.D. 8vo. Pp. 174. 1849.

The remedial powers of cod liver oil, although they have been greatly exaggerated, are still indisputable, yet many have been disappointed in the results they might reasonably have expected from its employment. Their failure may have been caused either by the cases chosen for its exhibition having been such as were not suited for the remedy, by the use of spurious oil, or by the various specimens of genuine cod liver oil, differing in their therapeutic efficiency. The Work of which we are about to give our readers some account, is chiefly devoted to a consideration of the comparative value of the three kinds of oil ordinarily found in the market, viz., the pale, light-brown, and brown. It contains a careful inquiry into the species of fish which yield these oils, the mode of their preparation, an elaborate chemical analysis of each kind, and an examination of their therapeutic action. Its accuracy has been acknowledged, and its importance appreciated in Germany, and the Profession of this country are indebted to Dr. Carey for placing it within their reach by his careful translation.

Dr. de Jongh informs us that cod-liver oil is prepared from almost all the species of the genus gadus. The Bergen oil, which alone is officinal in Germany, is the produce of three species of the above genus. The physical and chemical characters of the oil depend on the mode of preparation, and not on the species from which it is obtained. Dr. de Jongh took the greatest pains to ascertain the truth of this assertion. From the trustworthy accounts of some wholesale merchants, he learned the following particulars:—

"The pale oil is obtained by the spontaneous flow from the putrescent livers; the brown by the boiling or roasting of the livers, from which, at an ordinary temperature, nothing is obtained. The light brown oil is a pale, clear oil, which either has stood long on the livers, or has got old in the warehouses."

The physical characters of the brown oil, which, according to our Author's own researches, exhibits more powerful therapeutic effects than the pale or light brown, are thus detailed:—

"Colour, dark brown, by a reflected light green, in small portions transparent; a peculiar, disagreeable, and empyreumatic smell; bitter and empyreumatic taste, strongly irritating the fauces; slightly acid with litmus paper. While the pale oil is described to be of a gold yellow colour; a peculiar, but not disagreeable smell; a fishy, not bitter, slightly acid, taste. The pale brown oil possesses physical characters intermediate between the two former."

The fact of a considerable quantity of spurious oil having found its way into the market, rendered it very desirable that some certain test of the genuine oil should be discovered. The presence of iodine is such a test. The Practitioner may reject as spurious all oil which contains no trace of iodine. This element may be found, although in different proportions, in the three varieties of the oil. The light brown contains the largest quantity, viz., 0·0406 per cent.; the brown the least, 0·0295 per cent. only. The iodine is never free in the oil, nor in the form of iodide of sodium, but is in every case found to be in organic combination with fatty substance.

The best method of discovering the existence of iodine is thus given:—

"The oil is saponified with pure potash in excess; the soap formed is carbonized in a platinum crucible, and then saturated with carbonate of ammonia, and dissolved in water or alcohol. In the latter case a nearly pure iodide of potassium is obtained."

The iodine can of course be then readily detected by the blue colour, produced by the addition of starch and sulphuric acid. The chemical differences between the pale and brown oils may be generally stated thus,—the pale oil contains more oleic acid, but less of all the other organic constituent, especially of the biliary matters than the brown; while the latter contains less of the inorganic constituents than the former.

The historical notices are full. We learn that Eng-

land has the honour of having been the first to introduce into use cod liver oil as a medical agent. It was prescribed in chronic rheumatism by Dr. Perceval in 1771, and was subsequently used in the Infirmary at Manchester by Ray and Bardsley. In 1822, Schenk tried it in rickets and other scrofulous affections. From that time the drug has continued to rise in the estimation of the Profession. However, it did not come into general use for some years. In 1841, Dr. Hughes Bennett published an Essay on its therapeutic powers. The favourable impression produced by that Treatise induced Mr. Chalk, then of the Margate Infirmary for scrofulous and chronic affections, to use it extensively, and shortly after to publish a series of forty cases, in the majority of which it proved highly beneficial. From this time it has held a high place in the esteem of the Profession of this country.

It is unnecessary to lead our readers through Dr. de Jongh's account of the value of the oil as a means of cure in the different diseases for which it has been recommended, but there is one point to which we must allude, and that is, the great advantage which would be conferred on practical medicine by a careful analysis of two series of cases of phthisis, in which the oil had been administered on the one hand with advantage, and on the other with little or no benefit.

There cannot be a question, that under the term phthisis more than one disease has been confounded. That every case of chronic consolidation, with subsequent excavation of the apex of the lung, is not dependent on scrofula, and, therefore, phthisis and scrofula are not necessarily co-existent; or, in other words, phthisis, in the ordinary acceptation of the word, may occur where no scrofulous taint, hereditary or acquired, exists. (See some very able papers by Dr. Addison in Guy's Hospital Reports.) Sebastiani is quoted as saying, "I have found the cod liver oil to be most serviceable in cases of *hereditary* phthisis." As the iodine is found in somewhat larger proportion in the pale than in the brown oil, and yet the latter is the most efficacious, Dr. de Jongh supposes that the therapeutic powers of the oil depends chiefly on the butyric acid it contains. That the iodine, although existing in such very small proportion, is really active, is proved by the fact, that it can be detected in the urine of persons taking cod liver oil.

To ascertain the comparative effects of the three oils, our Author proceeded thus:—To the first six cases that fell under his observation, which he thought suited for the exhibition of the remedy, he administered the brown oil; to the next six the light brown, and to a third series of six the pale. The result, which Dr. de Jongh has detailed at length, was, that the brown cod liver oil generally effected cures in half the time required by the pale or light brown oil.

But it is not easy to obtain *pure* cod oil. That which comes from Rouen and the coasts of Normandy, is obtained from the boiled livers of ray-fish, *R. bates* and *R. clavata*; a variety from Norway is procured from the roes and entrails of the gadus species boiled together; and some sent from Senegal to France is obtained by roasting the entrails of a species of a crab, *C. ruricola*. Under these circumstances, it is gratifying to know that a highly respectable English house, Messrs. Langton Brothers and Scott, of Upper Thames-street, have established a manufacture of cod oil at Newfoundland, under the management of Mr. Fox, of Scarborough, well known as the maker of some of the best that has come to market. We have received a specimen of their oil; it is remarkably pure, and we strongly recommend it to the consideration of our readers.

ON THE MANUFACTURE OF SUGAR.

[To the Editor of the Medical Times.]

SIR,—In your recent Review of my Book on the Sugar Manufacture, you speak of the very natural prejudice against the use of a salt of lead. Permit me, therefore, to draw your attention to the following facts.

The acetates of lead are, and long have been, extensively employed in the sugar manufacture—some operators attempting to remove any excess of that salt which might exist, by the careful addition of dilute sulphuric acid—whilst others, and by far the greater portion, *never attempted the removal of any such excess at all*, merely relying on what I would term a timid primary apportionment. One foreign refiner candidly owned to me that he used the acetate of lead habitually for sugar of a certain class, and employed *no means* for separating any excess of acetate which might exist.

I asked him whether his products would not, on examination, yield evidences of the presence of lead. He said, "Most likely;" but that "he guarded against this in some respect by incorporating results made by means of lead, with others made without."

Even many of such manufacturers as never employ this agent, nevertheless impart a considerable amount of lead in a soluble, and therefore poisonous, condition to their resulting staple, owing to the leaden tanks which are employed by them as vessels of capacity. I have now in my possession a sample of sugar solution, taken at random from one of the largest refiners in London. This samples is largely contaminated with lead from the latter cause, as I demonstrated to the refiner in his own manufactory.

The process introduced by me is one emphatically for rendering lead harmless, which it does by generating the sulphite of the oxide of that metal. This sulphite is subsequently filtered away with the greatest ease. Should, however, a portion come through the filter, no harm can result, as the sulphite of lead is not a poisonous agent.

Indeed, the process has been carried on now for a considerable time in a refinery on the large scale, and in Cuba it is now conducted by slaves, in both cases with the most complete success. I have a sample of sugar from this latter source, sent home at random. It is totally free from lead in any state of combination. With these facts before me, I need hardly say I require no authoritative opinions for my own satisfaction; nevertheless, others interested with me in the extension of this process have obtained the testimony of some of the leading chemists of Britain, as you may see by the enclosed document, (a) which you may publish if you think fit.

I have the honour to be, Sir,
Your obedient servant,
JOHN SCOFFERN.

30, Essex-street, Strand.

CHOLERA IN DUMFRIES.

[To the Editor of the Medical Times.]

SIR,—On my return from the Continent, about ten days since, my attention was directed to a communication from Dr. Grieve, published in your Journal of May 26th, 1849, styled "Practical Observations on Epidemic Cholera, as it appeared in Dumfries during 1832 and 1848." Now, being engaged, through its late visitation (1848) as house-surgeon to the Dumfries Infirmary, to which many of those observations bear reference, I feel called upon to correct an error made (no doubt unwittingly) by my respected friend, regarding the propagation of cholera by contagion, a point on which so many are at variance at present, and in a Journal of such extensive circulation, and so highly valued, as the *Medical Times*, a letter of the kind must influence many in forming their opinions. On looking over the Hospital Reports for 1832, when no persons affected with the epidemic obtained admission, I find there was not one in-patient in which even the premonitory symptoms presented themselves. In 1848, on the other hand, on the admission of the fourth case, our cholera nurse was seized with and fell a victim to the disease. With the exception of one male nurse, (Hugh Geddes,) all those belonging to the Infirmary, and all the patients, except two surgical, suffered more or less severely from premonitory symptoms, *i. e.* diarrhœa and sometimes cramps. Of the two who escaped, one (Charles Carlon) suffered from scrofulous degeneration of the tarsus, from which there were numerous sinuses discharging profusely. The other, (John Ker,) in connexion with scrofulous knee-joint, had also numerous abscesses draining the system at the time of the epidemic.

Of the medical men employed in Dumfries, four were attacked by and went through all the stages of cholera, few of the others escaping some of its symptoms. The cases which Dr. Grieve adduced, where persons had slept with impunity in the bed of a cholera patient, do not prove the non-contagious properties of the disease, but merely, that the persons so placed were in a state of mind capable of resisting the poison.

In connexion with the electric shock experienced from contact with a cholera patient, Dr. Grieve, without detracting at all from the merits of his paper, might have mentioned my name as the first who called his attention to the subject. This thrilling sensation, resembling that from an electric machine, is more powerful along the course of large arteries (radial pulse) and in the early stage of collapse, at which time, also, the earthy fetor is more perceptible. To these particulars I drew the attention of some physicians and students in the Paris Hospitals, who were not previously aware of its existence. Allow me to mention one thing further in reference to that very distressing symptom, *i. e.* hiccough, which almost always occurs in the last stage of collapse, either immediately preceding dissolution or the consecutive fever; the only remedy I have known perfectly successful in hospital practice was sinapism or blister to the nape.

Trusting these few remarks may be taken as communicated—in friendly part,

I am, your most obedient,
JAMES SMYTH.

Dromore House, Coleraine, Aug. 16, 1849.

[We beg to assure Mr. Smyth that the "thrilling sensation" to which he alludes was well known to the numerous body of Medical men congregated in Dumfries in 1832, and among whom was Dr. Grieve. —ED.]

(a) Dr. Scoffern has placed in our hands certificates from some of the first chemists in Great Britain, with which, however, it is unnecessary to trouble our readers.—ED.

GLYCERINE IN DEAFNESS.

[To the Editor of the Medical Times.]

SIR,—In your Report of the proceedings of the Provincial Medical Association at Worcester, occurs an error which I am most anxious should be corrected. To me is ascribed the introduction of the oil of glycerine as a remedy for deafness!

I hope I may be never guilty of anything half so absurd as to recommend this or any other lubricating fluid to be applied to the outer passages of the ear, as a curative agent in deafness. For years past I have denounced, in my writings, all such antiquated notions of treatment, which ought not to be talked of in the nineteenth century, and in the present state of our knowledge of diseases of the ear. The mistake has arisen, no doubt, from the parties who really proposed the use of glycerine, having so mixed up my new treatment of diseased tympana by the introduction of a piece of cotton, moistened in distilled water in a peculiar manner and to a particular spot in the passage of the ear, with their new remedy, that, unfortunately, it is difficult for anybody, unacquainted with the facts, to separate the metal from the dross.

Glycerine was proposed to me by Mr. Barrett, of Bath, on the first publication of my papers in the *Lancet* twelve months ago, as a substitute for water in moistening the cotton-wool, and rejected for the same reasons I had rejected all other oily fluids. As a curative agent, *per se*, the common sense of the Profession will rise up against it and reject it.

I am not aware that any account of the singular discovery it has been my good fortune to make has yet appeared in the pages of the *Medical Times*. I hope to have the pleasure of sending you a paper on the subject for insertion in an early Number of your Journal.

Begging that this disclaimer may appear in your next Number,

I have the honour to be, Sir,
Your obedient servant,
JAMES YEARSLEY.

15, Savile-row, Aug. 20, 1849.

THE CONVENTION OF POOR-LAW MEDICAL OFFICERS AND THE MEDICAL CORPORATIONS.

[To the Editor of the Medical Times.]

4, Hanover-square, Aug. 21, 1849.

SIR,—I am desired, by the Committee, to request the favour of your publishing, in the next Number of the *Medical Times*, the following copy of a letter addressed to the Royal Colleges of Physicians and Surgeons, and the Apothecaries Society, together with the answers received from those bodies in reply to that communication.

I am, Sir, your most obedient servant,
CHARLES F. J. LORD, Hon. Sec.

(Copy.)
Committee of Poor-law Medical Officers,
4, Hanover-square, July 27th, 1849.

Gentlemen,—Remembering the courteous recep-

tion given last year by you to the Deputation, and the assurance of sympathy and promises of co-operation with which they were favoured, the Committee feel that they would be blameable if they did not now point out the manner in which your influence may be beneficially exercised in their behalf.

A second Deputation from the Committee having been received recently by the President of the Poor-law Board, the Committee are of opinion, that the general interests of the Union Surgeons may be advanced by your College memorializing the Poor-law Board, and petitioning both Houses of Parliament in favour of an improved system of Medical relief to the sick poor.

The plan submitted last year as suggestions to Sir George Grey, is by no means binding in detail, although the three grand features of it are still held by the Committee to be as essential to the best interests of the sick poor as they are to the just position and equitable though modest requital of the Poor-law Medical Officers.

These, as set forth in a recent Petition to Parliament, adopted and numerously signed, at a large meeting presided over by Lord Ashley, consist—

1st. In permanence of appointment during the capability and good conduct of the Medical Officer.

2nd. In payment proportioned to the extent and character of his duties.

3rd. In responsibility to Professional authority through a Medical Board.

The Committee hereby beg the favour of your applying to the Poor-law Board and to Parliament in favour of these principles, as a step conducive to the interests of the sick poor, of the Profession generally, (the Union Medical Officers more especially,) and of society at large.

We have the honour to be, Gentlemen,
Yours very respectfully,
THOMAS HODGKIN, M.D., Chairman.
CHARLES F. J. LORD, Hon Sec.
To the President and Censors of the
Royal College of Physicians.

(Copy.)

College of Physicians, July 3rd, 1849.

Sir,—Your letter of the 27th ult., addressed to the President and Censors of the Royal College of Physicians, has been laid before their Board, and in reply to it, I am directed to state to you, that their Board has already petitioned the House of Commons in favour of the suggestions made at the meeting, which was presided over by Lord Ashley.

I have the honour to be, Sir,
Yours very respectfully,
FRANCIS HAWKINS, M.D., Registrar.
To the Chairman of the Committee of
Poor-law Medical Officers.

Royal College of Surgeons of England,
3rd of August, 1849.

Sir,—I am desired by the Council of this College to express their unchanged desire to promote the interests of the Poor-law Medical Officers.

At the same time, the Council feel considerable difficulty in complying with the wishes of the Convention, that this College should memorialise the Poor-law Board, and petition both Houses of Parliament; and this, in consequence of the probability, should former precedents be adopted, of the case of the Poor-law Medical Officers being referred to this College for their opinion.

The Convention ... be pleased, also, to bear in mind, that the Council of this College, in making any such representation to the Poor-law Board and to the Legislature, as might effectually support the claims of the Union Surgeons, would be expected to found their application, not on evidence furnished by the parties aggrieved, which would be considered an *ex-parte* statement, but on the actual knowledge by the Council of facts, which they, unfortunately, have not the means of ascertaining.

The Council are prepared, indeed, to view favourably the adoption of the three grand features of the plan submitted to Secretary Sir George Grey, viz.;—

1st. In permanence of appointment during the capability and good conduct of the Medical Officer.

2nd. In payment proportioned to the extent and character of his duties.

3rd. In responsibility to professional authority through a Medical Board.

The Council beg to remark, however, with respect to the third proposal, that they are not prepared to recommend a "Medical Board," until informed of the proposed constitution thereof.

And that, on the whole, they believe the most satisfactory arrangement to all parties would be, the appointment of a Medical Inspector in each district, under the charge of an Assistant Poor-law Commissioner.

I have the honour to be, Sir,
Your most obedient servant,
EDMUND BELFOUR, Secretary.
To Dr. Hodgkin,
Chairman of Committee of Poor-law Medical Officers.

Apothecaries' Hall, 13th July, 1849.

Sir,—I am directed, by the Master and Wardens of the Society of Apothecaries, to acknowledge the receipt of your letter of the 27th ultimo, which they have only to-day had an opportunity of laying before the Committee of the Society. The Master and Wardens will thank you to favour them with a copy of the Petition to Parliament to which you refer in your letter, and with a statement of any plan which the Convention may have matured, with the view of carrying out the principles laid down in that Petition into practical operation.

With this information before them, the Society will be happy to take the subject into their further consideration.

Will you, at the same time, be good enough to state what communication has taken place between the Convention and the other Medical Corporations, as it is obviously desirable that the Medical Corporations should act in harmony on this subject.

I am, Sir, your most obedient Servant,
ROBERT B. UPTON,
Clerk to the Society.
C. F. J. Lord, Esq., Honorary Secretary.
Convention of Poor-law Medical Officers,
4, Hanover-square.

THE LATE SIR CHARLES SCUDAMORE.

Sir Charles Scudamore was born at Wye, in Kent, in 1779, and married, in 1812, Georgina, second daughter of Robert Johnson, Esq., of Finchley, Middlesex.

The family of Scudamore is of great antiquity, and claims descent, through the Kentish branch, with the ancient house of Holm Lacy, in Herefordshire.

The subject of our present Memoir received his early education at Wye College, under the Rev. Philip Parsons, and there distinguished himself, by his assiduity in the study of the Classics, English Literature, and the Belles Lettres. He afterwards commenced his medical studies, under the tuition of his father, a highly-esteemed Medical Practitioner at Wye, and an elegant scholar. Sir Charles's energies were, in due time, transferred to a more extensive field; and the area of the Borough Hospitals being the chosen theatre, and Cline, Saunders, Babington, Cooper, and other distinguished men, his teachers, his thirst for medical knowledge increased, and his acquirements became enlarged. After remaining three years at Guy's and St. Thomas's Hospitals, where he gained the esteem of his teachers, he established himself at Highgate, as a Surgeon, which step he considered only as a preliminary one to the higher views on which, from the commencement of his medical studies, his mind had been fixed. Remaining a few years at Highgate, he fulfilled his desire of acquiring professional experience, and proceeding to Edinburgh, devoted himself to his studies with intense ardour, and became noticed by the most eminent men there. At Glasgow, he took his degree, and wrote an elaborate Thesis on Gout, which he dedicated to Dr. Babington, of London, and Dr. Browne, the celebrated Professor of Moral Philosophy in Edinburgh. Dr. Scudamore then returned to London to practice as a Physician, residing first in Holles-street, and shortly after in Wimpole street, where he remained until his death. Soon after coming to London, he published an Analysis of the Mineral Waters of Tunbridge Wells, in which he was assisted by his friend, Mr. John George Children; also, the first edition of his work on Gout, which he dedicated to Dr. Matthew Baillie. This work quickly gained for its author a high reputation, was eagerly sought for, and passed through four editions in the course of six years. In the next five years, his practice became most brilliant and extensive; his patients (from the nature of the disease in which he had become so eminent) were of the very highest class, and amongst them might be enumerated a large number of the nobility and leading men of the day. He was appointed Physician in Ordinary to His Royal Highness Prince Leopold of Saxe Coburg, in 1820, and to the Duke of Northumberland, when Lord-Lieutenant of Ireland, from whom he received the honour of knighthood. He was also made Honorary Member of Trinity College, Dublin; of the Imperial College of Vienna; of the Medical Society of Paris; Fellow of the Royal Society of London, &c.

Among numerous works on different diseases, published by Sir Charles, may be mentioned, "A Treatise on the Nature and Cure of Rheumatism and Tic Doloureux;" "An Essay on the Blood," containing many original observations, and displaying much physiological and scientific research;" "Observations on the Stethoscope and Percussion," published after studying the subject in Paris under Laennec; "An Analysis of all the important Mineral Springs in England;" "A Treatise on the Mineral Waters and Tepid Springs of Buxton;" in which last works he was assisted by Mr. Garden (the well-known operative chemist of Oxford-street, London); and two short treatises, containing the result of his extensive experience in gout, and on the use and abuse of colchicum in the treatment of that disease. His later works were on the use of the inhalation of iodine and conium in phthisis, and an account of a medical visit to Graffenberg, made in the year 1843, for the purpose of investigating the merits of the water-cure treatment. The last contribution to Medical Science, published by him in 1847, was a work on pulmonary consumption.

Sir Charles was attacked with spasmodic asthma in January last, and more recently suffered from granular disease of the kidneys and valvular disease of the heart, from which latter affection he died suddenly on the 4th instant, much regretted and beloved by a numerous circle of friends.

BENEVOLENT FUND OF THE PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

We have great pleasure in presenting to our readers the following extract from the "Report" of the Benevolent Fund of the Provincial Medical and Surgical Association for the year 1849. It was our intention to have added a few lines of commendation; but the excellent "Appeal" by Mr. Newnham which precedes it, has rendered that unnecessary. Our earnest wishes are for its success.

"APPEAL ON BEHALF OF THE MEDICAL BENEVOLENT FUND, ESTABLISHED 1836.

"'To do good and to distribute, forget not, for with such sacrifices God is well pleased.—Heb. xiii. 6.'

"The Medical Benevolent Fund was instituted in the year 1836, for the purpose of affording relief to Medical Men under circumstances of temporary distress, (from sickness and misfortune,—or when incapacitated from active exertion by old age; and it embraces also the widows and orphans of such regularly educated men, when they have been left in situations of great poverty and indigence.

"This fund requires no other test or qualification for an admission to its relief, than the facts, that the party has been regularly educated,—that he is in indigent circumstances,—and that his poverty has been the result of misfortune,—not of misconduct. In these respects, it differs from other funds which require the qualification of pecuniary membership for a given time, and a residence within a prescribed district; and it is especially devoted to a species of misery, which cannot be relieved by the local funds; so that wherever there exists sickness and sorrow to be soothed—or hunger and destitution to be alleviated, there is ever at hand, the peculiar agency of the Benevolent Fund.

"For thirteen years, this Institution has pursued its unwearied course of benevolence,—and during that period, has relieved a mass of misery altogether incalculable. In the last twelve months it has extended its aid to 34 cases of urgent distress, comprehending 14 Practitioners under varied forms of suffering. *One* of these was supported during the last months of a pitiable existence; *six* were relieved from present emergencies; and *seven* were re-instated in their professional employment. Under this class, should be added 38 individuals, comprising the wives and children of the above-named Practitioners. Relief has also been given to 16 widows and 28

orphans,—as well as to 10 adult orphans in the most straitened circumstances; and one wife and five children, have been supported for six months by by a weekly allowance, while deprived legally of the husband's assistance. These several classes comprise 120 individuals who have been relieved at a cost of about 470*l*.

"This Institution is composed of two branches, one, of subscriptions thus employed for the relief of present distress; and the other of donations, which are directed to accumulate till they reach 2,000*l*.; after which the accruing *income* may be applied in the form of annuity as may be required, or of loan for twelve months without interest, upon approved security. During the past year, more especially, the Committee have felt the cruel want of this fund, which at present reaches only about 1,550*l*.; and they believe that the time has arrived, when by a strenuous effort of themselves and their friends, they may be enabled to realize the 2,000*l*., the great object of their hopes, and to bring at once into operation this most important branch of their Institution. For this purpose they pledge their own exertions; and they appeal to all their subscribers and friends to aid them in this good work. They are, however, feelingly alive to the fact, that they would be seriously injured by the withdrawal of any subscriptions in order to convert them into donations; but they are assured, that the good sense and kind feelings of their friends will induce them not to diminish their own annual contributions; but, on the contrary, to canvass their friends for fresh subscriptions or donations, as may be most agreeable to them, and they especially ask for the agency and zeal, and untiring energy of those ladies who have been so justly described as 'ministering angels,' where pain, and sickness, and sorrow, and want, and misery, hold their tyrannous empire.

"It would doubtless aid the cause of the institution to give the details of a few of the harrowing cases relieved. But we dare not draw aside the veil of that 'sacred misery' which courts the sheltering retirement of obscurity, and shrinks from the glare of observation; we may not lay open to the common gaze the agonies of the riven bosom—nor the penury and starvation of the solitary garret—nor the dreariness of that widowed heart, which contemplates with anguish inexpressible the innocent faces of her thoughtless children, as yet all unconscious of the asperities of a selfish world.
